Heptazine,  $C_6N_7$ , 1,3,4,6,7,9b-heptaazaphenalene, which is also called tri-s-triazine or cyamelurine, consists of three fused triazine rings, typically with three substituents at the corners of the triangle [1276]. The name “hepta” initially conjures up the image of a seven-membered ring, however, this molecule is just a honeycomb of hexagonal rings with seven nitrogen atoms embedded, which explains the name hepta. Its skeleton structure is similar to that of the all-carbon phenalene, a polycyclic aromatic hydrocarbon. The parent compound  $C_6N_7H_3$ , where the three substituents are hydrogens, is called 1,3,4,6,7,9-hexaazacyclo[3.3.3]azine or tri-s-triazine proper. Heptazines

are used as flame retardants and have been proposed for applications in electronics materials, explosives, and gas generants.

Generic heptazine; R1, R2, R3 are arbitrary substituents

DFT techniques were used for the prediction of gas phase HOF of nitroheptazines, while crystal density was assessed by packing density calculations [1277]. The results revealed that nitro derivatives of heptazine possess a high HOF. Further enhancement was achieved by the substitution of nitrogen heterocycles. The crystal packing density of the designed compounds varied from 1.8 to 2 g/cm<sup>3</sup>, hence, of all the designed molecules, nitro derivatives of heptazine exhibit better energetic performance characteristics in terms of detonation velocity and pressure. 2,5,8-Tri(azido)-s-heptazine, 3,7,11-triazido-2,4,6,8,10,12,13-heptazatricyclo[7.3.1.0<sup>5,13</sup>]trideca-1(12),2,4,6,8,10-hexaene, 2,5,8-triazido-1,3,4,6,7,9,9b-heptaazaphenalene, C<sub>6</sub>N<sub>16</sub>, contains 75.67 mass-% N.

2,5,8-Triazido-s-heptazine, C<sub>6</sub>N<sub>16</sub> (TAH)

Derivatized s-triazine precursors can be used in the production of carbon nitride materials. Larger polycyclic molecular precursors, such as those containing an s-heptazine core (C<sub>6</sub>N<sub>7</sub> or tri-s-triazine), may improve stability and order in carbon nitride products. Synthesis of 2,5,8-triazido-s-heptazine was achieved from melon, an oligomeric s-heptazine synthesized by the pyrolysis of NH<sub>4</sub>SCN [1278]. Melon was converted to molecular 2,5,8-trichloro-s-heptazine, which was then transformed to triazide. The crystal structure of 2,5,8-triazido-s-heptazine was verified and showed that the s-heptazine is planar and that the azides adopt a pinwheel-like C<sub>3h</sub> arrangement around the periphery. 2,5,8-triazido-s-heptazine exhibits photoluminescence at 430 nm. It rapidly and exothermically decomposes upon heating at 458 K (185 °C) to produce a tan, thermally stable carbon nitride powder with a composition near C<sub>3</sub>N<sub>4</sub>.

2,5,8-Trihydrazino-*s*-heptazine  $C_6N_7(NHNH_2)_3$  can be obtained from melem  $C_6N_7(NH_2)_3$  or melon  $[C_6N_7(NH_2)NH]_n$  and hydrazine by an autoclave synthesis [1279]. Upon treatment with a 10% HCl solution, it can be transformed into the trihydrochloride  $[C_6N_7(NHNH_3)_3]Cl_3$ . These compounds were analyzed by  $^{13}C$  NMR,  $^{15}N$  NMR, XRD, FTIR, and Raman spectroscopy. The reaction of 2,5,8-trihydrazino-*s*-heptazine with  $NaNO_2/HCl$  yields triazido-*s*-heptazine,  $C_6N_7(N_3)_3$ .

## 20 Tetrazines

The most common tetrazine is the symmetrical 1,2,4,5-tetrazine,  $C_2H_2N_4$ , CAS RN [290-96-0],  $M = 82.064$  g/mol.

1,2,4,5-Tetrazine

Tetrazines have highly positive enthalpies of formation and high crystal densities. These are desirable properties for a HEDM backbone. Relatively few unsubstituted tetrazine compounds have been evaluated as rocket propellants. Most of the work was conducted with tetrazines that had amino, hydrazino, nitramino, or guanidino groups attached in the 3- and 6-positions [1012]. These amines form high-energy salts with oxygen-containing mineral acids. With strong nitric acid, tetrazine can also form tetrazinium(2+) dinitrate salts [1280]. There have been numerous efforts to develop and improve tetrazine-based molecular and ionic energetic compounds [1281], such as by linking or fusing tetrazine rings with furazan rings or pyrazole rings [1, 11, 1282–1284].

### 20.1 Molecular Structure of Tetrazines

The thermal decomposition pathways of the *s*-tetrazine molecule and five of its derivatives were simulated by an AIMD method to predict the possible decomposition pathways and identify their relative importance [1285]. The reaction channels were studied by DFT methods to locate the local minimum points and the transition structures. It was also used to verify the result of the AIMD method in terms of energy, with findings suggesting that the *s*-tetrazine molecule underwent concerted triple dissociation. The effect rules of five different substituents on the modes of the tetrazine ring-opening, the stability of the tetrazine ring, and the thermal decomposition mechanism of tetrazine derivatives were investigated. If the stability of the substituent is better than that

of the tetrazine ring, decomposition occurs first through the ring breaking. Otherwise, the substituent reactions first take place.

Dihydrotetrazine can undergo isomerization reactions. A study of the mechanism of hydrogen transfer isomerization reactions for dihydrotetrazine indicated that the reaction is an endothermic and unspontaneous process at room temperature [1286]. The obtained results indicated that the variational effects are small over the whole temperature range, while the tunneling effects are remarkable at low temperatures (200–500 K).

*s*-Tetrazine crystals are monoclinic, space group  $P2_1/c$ . The crystal unit cell has the following dimensions:  $a = 5.23 \pm 0.01 \text{ \AA}$ ,  $b = 5.79 \pm 0.01 \text{ \AA}$ ,  $c = 6.63 \pm 0.01 \text{ \AA}$ , and  $\beta = 115^\circ 30' \pm 15'$  [1287]. The *s*-tetrazine molecule is a planar distorted hexagon with the following bond lengths and angles: C–N 1.334 Å, N–N 1.321 Å,  $\angle$ C–N–N  $115^\circ 57'$ , and  $\angle$ N–C–N  $127^\circ 22'$  [1288].

Although theoretically possible, 1,2,3,4-tetrazine (vicinal) and 1,2,3,5-tetrazine (unsymmetrical) do not exist and only a few derivatives with the isomeric arrangement of the four nitrogens in the ring other than the symmetric 1,2,4,5 arrangement are known [1289].

## 20.2 Thermodynamic Properties of Tetrazines

Thermodynamic properties and the thermal stability of tetrazines vary with the type of substituents. These properties can be determined by experiment or can be predicted by computational chemistry. There has been a flood of computational studies on tetrazines and other heterocyclic energetic compounds but very few have tested the accuracy of the predicted performance by comparing it with actual experimental data.

Substituted *s*-tetrazine compounds were designed and investigated to find comprehensive relationships between the structures and explosive performance of high-nitrogen energetic compounds [1290]. DFT was used to predict the optimized geometries, electronic structures, HOFs, and densities, and the detonation properties were calculated. Calculation results showed that there are good linear relationships between enthalpies of formation, densities, detonation properties, and the number of N atoms in many designed high-nitrogen compounds. Furthermore, several envisioned high-nitrogen compounds showed good predicted detonation velocities and pressures compared with HMX.

The HOFs for a series of 1,2,4,5-tetrazine derivatives were calculated by using DFT, Hartree Fork (HF), and MP2, and semi-empirical methods were utilized also [1291]. The results showed that –CN or –N<sub>3</sub> groups play a very important role in increasing the  $\Delta H_f$  values of 1,2,4,5-tetrazine derivatives. An analysis of the BDE for the weakest bonds indicated that substitutions by –N<sub>3</sub>, –NH<sub>2</sub>, –CN, –OH, or –Cl groups were favorable for enhancing the thermal stability of 1,2,4,5-tetrazine,

however,  $-\text{NHNH}_2$ ,  $-\text{NHNO}_2$ ,  $-\text{NO}_2$ ,  $-\text{NF}_2$ , or  $-\text{COOH}$  group produced the opposite effects. The calculated detonation velocities and pressures indicated that the  $-\text{NF}_2$  or  $-\text{NO}_2$  groups are very helpful for enhancing the detonation performance for the derivatives but the contrary applied for  $-\text{CN}$ ,  $-\text{NH}_2$ , or  $-\text{OH}$  groups.

### 20.3 Ring-Substituted Tetrazines

Tetrazine(s) are the building blocks for a wide array of energetic materials with potential uses as explosives or rocket propellants [1292]. The most desirable substituents are explosophoric groups like nitro or nitramino groups. In addition, one or two nitrogens in the ring can be oxidized to form *N*-oxides.

### 20.4 Di-Substituted Tetrazines

#### 20.4.1 Diaminotetrazine

3,6-Diamino-1,2,4,5-tetrazine,  $\text{C}_2\text{H}_4\text{N}_6$ , DATZ, DATz, CAS RN [19617-90-4], is a symmetrical molecule and has a molecular mass of 112.0934 g/mol. It is a precursor for the synthesis of many more energetic molecules such as 3,6-diamino-1,2,4,5-tetrazine 1,4-dioxide.

The reaction of triaminoguanidinium chloride with 2,4-pentanedione produced 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2-dihydro-1,2,4,5-tetrazine in 80–85% yield. Oxidation of bis(3,5-dimethylpyrazol-1-yl)-1,2-dihydro-1,2,4,5-tetrazine with nitric oxide or nitrogen dioxide leads to 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, followed by ammonolysis, which produced 3,6-diamino-1,2,4,5-tetrazine in good yields [1293–1295]. 3,6-Diamino-1,2,4,5-tetrazine melts at 477–478 K (204–205 °C) [1296]. 3,6-Diamino-*s*-tetrazine (DATz) and some other *s*-tetrazine high-nitrogen energetic compounds were synthesized and characterized by IR, elemental analysis, NMR, and DSC at different heating rates [1283].

The enthalpies of formation and densities of six mono-substituted and six di-substituted tetrazine derivatives were calculated using a DFT method [1297]. The values were then used to predict the detonation velocity and detonation pressure of these compounds. The substituents were amino, hydrazino, carbamido, semicarbazido, 2-semicarbazido, and carbohydrazido groups.  $-\text{NH}_2$ ,  $-\text{NHNH}_2$ ,  $-\text{NHCONH}_2$ , and  $-\text{NHCONHNH}_2$  groups showed a strong electrophilic effect when connected with the tetrazine, especially the  $-\text{NHCONH}_2$  group. The predicted properties of 3,6-diaminotetrazine and 3,6-dihydrazinotetrazine are listed in Table 75. The 3,6-dihydrazinotetrazine was predicted to have the worst thermal stability of the twelve compounds examined.

Table 74 demonstrates a predicted  $\Delta H_f^0_{298} = +319.29 \text{ kJ/mol}$  but other sources reported a  $\Delta H_f$  for 3,6-diaminotetrazine as  $+307 \text{ kJ/mol} = +73.37 \text{ kcal/mol}$  [1298]. More

**Table 75:** Predicted properties of 3,6-diaminotetrazine and 3,6-dihydrazinotetrazine.

| Compound name            | Nitro-<br>gen<br>content | $E_{\text{TOTAL}}$ | $\Delta H_f^0_{298}$ |          | Density           | Deto-<br>nation<br>velocity | Deto-<br>nation<br>pressure |
|--------------------------|--------------------------|--------------------|----------------------|----------|-------------------|-----------------------------|-----------------------------|
|                          | Mass %                   | kJ/mol             | kJ/mol               | kcal/mol | g/cm <sup>3</sup> | km/s                        | GPa                         |

| 3,6-Dihydrazinotetrazine | 78.84                    | -1358.18           | +425.56              | +101.7   | 1.64              | 7.36                        | 22.67                       |

Data source: [1297].

recent sources reported a HOF of  $71.2 \text{ kcal/mol} = +297.9 \text{ kJ/mol} = 635 \text{ kcal/kg}$ , which may be an experimentally measured value [1299].

3,6-Diamino-1,2,4,5-tetrazine (DATz) was synthesized in 500g batches with a yield of 98.7% using 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine as the starting material [1300]. The structure of DATz was characterized by  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, FTIR, MS, and elemental analysis. The thermal decomposition behavior of DATz was studied by DSC, TGA-DTG, and *in-situ* RSFTIR. The crystal structure was determined by XRD. The crystals crystallized in orthorhombic shapes, space group *Cmcm*, with crystal unit cell parameters of  $a = 0.9431(4) \text{ nm}$ ,  $b = 0.7850(3) \text{ nm}$ ,  $c = 0.6267(3) \text{ nm}$ ,  $V = 0.464(3) \text{ nm}^3$ , and  $Z = 8$ ,  $\rho_c = 1.605 \text{ g/cm}^3$ . In the DSC, DATz had an exothermic decomposition peak with a peak at 615 K (342 °C) and had good thermal stability. The thermal decomposition of DATz starts by first breaking the tetrazine ring.

3,6-Diamino-1,2,4,5-tetrazine can be synthesized by nucleophilic substitution using 3,6-bis(3,5-dimethylpyrazol)-1,2,4,5-tetrazine as the precursor [1301]. As the next step, 3,3'-azobis(6-amino-1,2,4,5-tetrazine) (DAATz) can be obtained by the oxidative coupling reaction of DATz and 3,3'-diazenebis(*N*-(2,2,2-trinitroethyl)-1,2,4,5-tetrazin-6-amino) (BATAT) can be synthesized from 2,2,2-trinitroethanol and DAATz. The structure of BATAT was determined by MS,  $^1\text{H}$  NMR, and  $^{13}\text{C}$  NMR. The density, enthalpy of formation, detonation velocity, and detonation pressure of BATAT were calculated by a Monte Carlo method and the K-J equation. The predicted density, detonation velocity, and detonation pressure were  $1.827 \text{ g/cm}^3$ ,  $8.76 \text{ km/s}$ , and  $34.11 \text{ GPa}$ , respectively.

Oxidation of 3,6-diamino-1,2,4,5-tetrazine with peracids produced 3,6-diamino-1,2,4,5-tetrazine 1,4-dioxide as a major product [1302]. However, treatment of 3,6-diamino-1,2,4,5-tetrazine with peroxytrifluoroacetic acid produced only 3,6-diamino-1,2,4,5-tetrazine 1-oxide as a major product, along with a small amount of 3-amino-6-nitro-1,2,4,5-tetrazine 2,4-dioxide. All attempts to obtain 3,6-dinitro-1,2,4,5-tetrazine by this way failed.

3,6-Diamino-1,2,4,5-tetrazine-1,4-dioxide is also known under the code name LAX112. LAX112 has a very high detonation velocity of  $8300 \text{ m/s}$  and has been tested as an explosive in comparison to TNAZ and 2,4-DNI [104].

### 20.4.2 Dihydrazinotetrazine

3,6-Bis-(3,5-dimethylpyrazol-1-yl)-s-tetrazine (BDT) can be reacted with hydrazine and refluxed in acetonitrile to form 3,6-dihydrazino-s-tetrazine, also known as 3,6-dihydrazino-1,2,4,5-tetrazine; 1,2-dihydro-1,2,4,5-tetrazine-3,6-dione dihydrazone; 1,2,4,5-tetrazine, 3,6-dihydrazinyl-; dihydrazinotetrazine, 1,2-dihydro-1,2,4,5-tetrazine-3,6-dione hydrazone, (6-hydrazino-1,2,4,5-tetrazin-3-yl)hydrazine,  $C_2H_6N_8$ , DHT, CAS RN [5940-53-4],  $M = 142.13$  g/mol. DHT melts at 434–436 K (161–163 °C), has a density of  $1.667$  g/cm<sup>3</sup>, and has an enthalpy of formation of  $+535$  kJ/mol ( $+128.0$  kcal/mol =  $+901$  cal/g). Other sources gave the melting point as 410–411 K (137–138 °C). It can exist in two tautomeric forms.

3,6-Dihydrazino-1,2,4,5-tetrazine (DHT)

Some properties of DHT have already been listed in Table 75. 3,6-Dihydrazino-1,2,4,5-tetrazine is a very energetic molecule with a highly positive enthalpy of formation ( $+577$  kJ/mol) due to the N–N single bonds of the hydrazine moiety and the aromatic N–N bonds of the 1,2,4,5-tetrazine. The nitrogen content is 78.84 mass-% N. It can serve as a doubly charged cation to create 1:2 or 1:1 salts.

DHT is an example of a high-nitrogen, oxygen-free explosive that relies entirely on its HOF for sustaining a detonation. The density of DHT is  $1.69$  g/cm<sup>3</sup>. Other sources report a density of  $1.61$  g/cm<sup>3</sup> [1303, 1304] or  $1.667$  g/cm<sup>3</sup>. The predicted HOF of DHT in the gas phase is  $+640$  kJ/mol ( $+153$  kcal/mol). The heat of sublimation of DHT is  $105$  kJ/mol ( $25$  kcal/mol). The measured enthalpy of formation of solid DHT is  $+536$  kJ/mol ( $+128$  kcal/mol). The predicted detonation velocity is  $D = 8319$  m/s and the predicted C-J pressure is  $P = 30.41$  GPa [1305].

Other sources of DHT properties reported the following findings:  $\rho = 1.69$  g/cm<sup>3</sup>; auto-ignition temperature  $T_i = 437$  K =  $164$  °C;  $\Delta H_f = +535.5$  kJ/mol =  $+128$  kcal/mol =  $900$  kcal/kg; measured detonation velocity  $D = 7540$  m/s at a packing density of  $1.56$  g/cm<sup>3</sup> [1299]. The vapor pressure of DHT can be expressed by the equation

$$\ln p = 16.4 - 11410/T$$

where  $p$  is the vapor pressure in atm and  $T$  is the temperature in kelvin. The heat of sublimation is  $95$  kJ/mol ( $22.7$  kcal/mol). The dinitrate salt of DHT has a density of  $\rho = 1.80$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_{ign}$  of  $429$  K ( $156$  °C), and an enthalpy of formation  $\Delta H_f$  of near zero. The diperchlorate salt of DHT has a density of  $\rho = 1.96$  g/cm<sup>3</sup>, an auto-ignition temperature of  $593$  K ( $320$  °C), an enthalpy of formation of  $\Delta H_f = +711$  kJ/mol ( $+170$  kcal/mol =  $685$  kcal/kg), and a detonation velocity of  $D = 7520$  m/s at a packing density of  $1.76$  g/cm<sup>3</sup>.

The thermal and EI ionization stabilities of eight 3,6-disubstituted-1,2,4,5-tetrazines were examined by tandem mass spectroscopy techniques to construct fragmentation pathways [1306]. Tetrazine ring structures were not maintained under EI ionization nor under conditions of thermal decomposition. Under EI ionization conditions, the tetrazines shared the same initial fragmentation pathways: elimination of two of the nitrogen atoms as  $N_2$  from the tetrazine ring and cleavage of the remaining N—N bond. This pathway was also applicable to thermal decomposition. However, the main route involved dissociation of the substituent group, in some cases assisted by proton transfer.

The thermal stabilities of 3,6-dihydrazino-1,2,4,5-tetrazine and its diperchlorate [ $Hz_2Tz(HClO_4)_2$ ], dinitrate [ $Hz_2Tz(HNO_3)_2$ ], bisdinitramidate [ $Hz_2Tz(HDN)_2$ ], and bisdinitroimidazolate [ $Hz_2TzBim$ ] salts have been examined and compared to other 3,6-disubstituted tetrazines [1307]. The neutral tetrazines exhibited two principal modes of decomposition. The elimination of  $N_2$  from the tetrazine ring was followed by cleavage of the remaining N—N bond and loss of the substituent group (in some cases, this was assisted by proton transfer). The salts undergo reversible equilibrium with the parent amine and the proton donor. Thus, in several cases, the decomposition rate of the parent tetrazine amine and the salt were essentially identical. For a comparison of DHT with other tetrazine derivatives, see also [1308].

1,4-Dihydrazinotetrazine (DHTz) along with 3,3'-diamino-4,4'-azoxyfuran (DAAF) and 3,3'-azobis(6-amino-1,2,4,5-tetrazine) (DAAT) were synthesized and characterized by IR, NMR, MS, TG-DTA, DSC, TG-FTIR, impact, and friction sensitivity tests [682]. DAAF is insensitive to mechanical stimuli whereas DAAT and DHTz are vulnerable to impact stimuli. The theoretical explosive power of DAAF, DAAT, and DHTz alone and their combinations with well-known IHE as well as that of propellants based on them were calculated.

3,6-Dihydrazino-1,2,4,5-tetrazine and several of its energetic salts were synthesized from readily available starting materials like triaminoguanidine and 2,4-pentanedione [1309]. The synthesis route described in the literature was scaled up safely. The synthesized compounds were characterized by IR, NMR, elemental analysis, and MS, and the explosive properties (impact and friction sensitivity) and thermal stability properties (TGA/DTG) were studied.

3,6-Dihydrazino-s-tetrazine (DHT) and several other s-tetrazine high-nitrogen energetic compounds were synthesized and characterized by IR, elemental analysis, NMR, and DSC at different heating rates [1283]. The results showed that DHT was stable up to 393 K (120 °C), with a maximum exotherm at 432 K (159 °C) and a heat of reaction  $\Delta H$  of 1843 J/g.

The thermal behavior of 3,6-dihydrazino-1,2,4,5-tetrazine was studied by DSC and TG-DTG [1310]. The decomposition process can be divided into two exothermic decomposition stages with apparent activation energy ( $E_a$ ) and pre-exponential constants ( $A$ ) of the two exothermic decomposition stages being 154.8 and 123.4 kJ/mol, and  $10^{16.63}$  and  $10^{9.48} s^{-1}$ , respectively. The critical temperature of thermal explosion

is 426 K. The specific heat capacity of DHT was determined by the micro-DSC method and a theoretical calculation method. The standard molar specific heat capacity was found to be  $183.6 \text{ J mol}^{-1} \text{ K}^{-1}$  at 298 K. The adiabatic time-to-explosion of DHT was calculated to be somewhere between 263 and 297 s.

3,6-Dihydrazino-1,2,4,5-tetrazine forms dimers in the vapor phase [1311]. DFT methods were used to predict the changes of thermodynamic properties from the monomers to dimers, with the temperature ranging from 200 to 800 K. It was found that the hydrogen bonds predominantly contribute to the dimers and that the binding energies are not determined by hydrogen bonding only.

The molecular structure of a single crystal of 3,6-dihydrazino-1,2,4,5-tetrazine (DHT) was determined by XRD [1312]. The crystal belongs to the monoclinic system with a  $P2_1c$  space group,  $a = 0.4032(4) \text{ nm}$ ,  $b = 0.5649(6) \text{ nm}$ ,  $c = 1.2074(14) \text{ nm}$ ,  $\beta = 99.32^\circ$ ,  $Z = 2$ , and  $V = 0.2714(5) \text{ nm}^3$ . The molecule is centrosymmetric. A three-dimensional herringbone-like pattern was formed with the extensive hydrogen bonds. The heat of combustion was  $1787 \text{ kJ/mol}$  and the autodecomposition explosion point was 454 K. The theoretical standard HOF calculated through an atomization energy method was  $1075 \text{ kJ/mol}$ , leading to a theoretical detonation velocity of  $9.27 \text{ km/s}$  and a detonation pressure of  $36.02 \text{ GPa}$ . Both are higher than those of either TNT or HMX.

The thermal stabilities of 3,6-dihydrazino-1,2,4,5-tetrazine (DHT) and 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylimino)-1,2,4,5-tetrazine (BTATz) were examined using isothermal and non-isothermal methods [1313]. The first stage of DHT decomposition is a redox process in which the tetrazine ring is reduced by the hydrazine group forming diaminodihydrotetrazine and molecular nitrogen. The reaction has a high activation energy of decomposition ( $240.6 \text{ kJ/mol} = 57.5 \text{ kcal/mol}$ ) in the temperature interval 523–607 K (250–334 °C).

3,6-Dihydrazino-1,2,4,5-tetrazine can be synthesized by hydrazinolysis of 3,6-bis-(3,5-dimethylpyrazolyl)-1,2,4,5-tetrazine or in four steps via triaminoguanidinium chloride and acetyl acetone, followed by oxidation with liquid  $\text{NO}_2$  in NMP or  $\text{NaNO}_2$  in  $\text{CH}_2\text{Cl}_2$ /glacial acid and substitution with hydrazine. Nine doubly protonated 1:1 and 1:2 bishydrazinium-tetrazine salts of highly energetic anions were synthesized and five of them were characterized by XRD, NMR, MS, IR and Raman spectroscopy, DSC, and elemental analysis [1314]. The energies of formation and the detonation parameters of the most promising candidates were calculated and compared to RDX. Sensitivity tests towards impact, friction, and ESD were carried out. These revealed that some of the compounds were more sensitive than RDX.

If one wants to formulate propellants with high-nitrogen compounds, it is important to know if the highly reactive chemicals are compatible with other constituents (e.g., binders) of the propellant. The interaction of 3,6-dihydrazino-1,2,4,5-tetrazine with the main components of solid propellant was studied by DSC and the interaction of DHT with a CMDB propellant was investigated by a curing experiment [1315]. The results revealed that there were no obvious interactions between DHT with HMX, CL-20, NC, aluminum powder, carbon black, polyethylene glycol, 2-nitrodianiline-

(2-NDPA), 1,3-dimethyl-1,3-diphenyl urea (C2), or diisocyanate (N100). There were strong interactions between DHT and NG, RDX, 3,4-dinitrofurazanofuroxan, *N*-guanylurea dinitramide (FOX-12), *N*-nitrodihydroxyethylamine-dinitrate (DINA), and resorcinol. The DHT/CMDB propellant mixture can catch on fire when the slurry of the propellant is cured at 343 K (70 °C) for about 40 min. DHT cannot be applied to double-base propellants where NG is the main component.

Dihydrazino-1,2,4,5-tetrazine was synthesized from 3,6-di(3,5-dimethylpyrazole)-1,2,4,5-tetrazine and combined with decahydrodecaboric acid [1316]. Dihydrazine-1,2,4,5-tetrazinium decahydrodecaborate was obtained by a neutralization reaction with a yield of 80% and characterized by IR,  $^1\text{H}$  NMR, and elemental analysis. The heat of combustion determined by oxygen bomb combustion was 37.5 kJ/g.

3,6-Dihydrazino-1,2,4,5-tetrazine (DHT) can be used as a burning rate modifier in solid propellants. The thermal decomposition characteristics of DHT and the influence of eight types of lead/copper compounds on the thermal decomposition of DHT were investigated by DSC and TGA-DTG [1317]. The results showed that there are two stages in the DHT decomposition process. The first stage is the main decomposition process, which is the ring opening of the tetrazine ring. The second stage is the decomposition of the condensed phase products of the first stage. The thermal decomposition peak temperature of DHT can be significantly decreased and the exothermicity of DHT can be increased by mixing DHT with lead or copper compounds. Copper compounds have a better effect on decreasing the decomposition temperature of DHT than lead compounds, while lead compounds are more effective in increasing the exothermicity of DHT than copper compounds. Compared with single lead or copper catalysts, a composite catalyst of both lead and copper can further reduce the decomposition temperature and increase the exothermicity of DHT decomposition.

3,6-Dihydrazino-1,2,4,5-tetrazine can be prepared via a hydrazine base substitution reaction using 3,6-bis(dimethylpyrazole)-1,2,4,5-tetrazine (BDT) as raw material [1318]. The conditions of DHT synthesis were optimized, resulting in a yield of 92% and purity of 98.5% (the literature yield was 77%). 3,6-Dihydrazino-1,2,4,5-tetrazinium(2+) dinitrate (DHTN) and 3,6-dihydrazino-1,2,4,5-tetrazinium(2+) diperchlorate (DHTP) were prepared and properties were determined. The yield of DHTN was 91%. The density  $\rho$ , decomposition peak temperature, detonation velocity  $v_{\text{det}}$ , drop weight impact sensitivity  $H_{50}$ , and friction sensitivity were  $\rho = 1.708 \text{ g/cm}^3$ ,  $377.6 \text{ K} = 104.5 \text{ °C}$ ,  $v_{\text{det}} = 8541.3 \text{ m/s}$ ,  $H_{50} = 38 \text{ cm}$ , and 4% for DHTN, and  $\rho = 1.765 \text{ g/cm}^3$ ,  $470.5 \text{ K} = 197.4 \text{ °C}$ ,  $v_{\text{det}} = 8882 \text{ m/s}$ ,  $H_{50} = 8 \text{ cm}$ , and 100% for DHTP, respectively.

Structures of the salts formed by 3,6-dihydrazino-1,2,4,5-tetrazine with  $\text{HNO}_3$ ,  $\text{HN}(\text{NO}_2)_2$ ,  $\text{HClO}_4$ , and  $\text{HC}(\text{NO}_2)_3$  were studied using dispersion-corrected DFT calculations [1319]. The intra-molecular hydrogen bond energies of the four salts were estimated using the quantum theory of atoms in molecules. The total hydrogen bond energies ( $\text{EH}_{\text{tot}}$ ) decreased in the order of  $\text{NO}_3^- > \text{N}(\text{NO}_2)_2^- > \text{ClO}_4^- > \text{C}(\text{NO}_2)_3^-$ .

The pressure dependence of the strand burning rates of DHT burning rate can be described by two laws for two pressure intervals, which are divided by a combustion

instability region [1299]. Pellets of DHT burn by themselves smoothly at pressures from 0.2 to 20 atm with a burning rate equation of

$$r_b = 3.63p^{0.69}$$

where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in atm. At 20 atm the burning rate becomes irregular but normal behavior resumes at pressures between 40 and 100 atm. The burning rate was expressed by the equation

$$r_b = 2.04p^{0.67}$$

where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in atm.

### 20.4.3 Azidotetrazines

3,6-Diazido-1,2,4,5-tetrazine, 3,6-bis(azido)-1,2,4,5-tetrazine; 1,2,4,5-tetrazine, 3,6-diazido-;  $C_2N_{10}$ , DiAT, DAT, CAS RN [5940-58-9],  $M = 164.088$  g/mol, is a high nitrogen content (85.36 mass-% N) heterocyclic compound. There is substantial interest in it as a propellant and gas generant ingredient. 3,6-Diazido-1,2,4,5-tetrazine melts at 403 K (130 °C) and had a density of 1.72 g/cm<sup>3</sup>. It contains no hydrogen; therefore the combustion products are water-free, which is of importance for applications such as in chemical or gas dynamic lasers where the infrared absorption of water would interfere.

3,6-Diazido-1,2,4,5-tetrazine (DiAT)

Carbon nitrides are of current interest due to their novel mechanical, optical, and tribological properties, including low density, extreme hardness, surface roughness, wear resistance, chemical inertness, and biocompatibility. These extremely hard diamond-like materials promise a variety of technological and biological applications. For example, they are used as biocompatible coatings on biomedical implants, battery electrodes, catalyst supports, gas separation systems, electronic materials, and humidity and gas sensors. Unlike carbon-based materials, applications of carbon nitrides are governed by their nitrogen content. As a consequence of this, extensive effort has been focused on the discovery of precursors along with the appropriate methods to control and increase the nitrogen content in carbon nitrides. Carbon nitrides  $C_3N_4$  (60.9 mass-% N) and  $C_3N_5$  (66.0 mass-% N) have been prepared using high-nitrogen 2,4,6-tri(azido)-1,3,5-triazine as the precursor. A different synthesis of the high-nitrogen compound 3,6-di(azido)-1,2,4,5-tetrazine (DiAT), from which carbon nano-spheres ranging from 5 to 50 nm and nitrogen-rich carbon nitrides  $C_3N_4$  and  $C_3N_5$  can be prepared, has been developed. This started with the readily

available 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, which rapidly reacted with hydrazine hydrate to produce 3,6-di(hydrazino)-1,2,4,5-tetrazine. This was diazotized in 3M HCl at 273K (0 °C) to yield 3,6-di(azido)-1,2,4,5-tetrazine [1320]. DSC revealed an onset of decomposition at 403K (130 °C), which coincided with the melting point. It is extremely sensitive to spark, friction, and impact.

The normalized HOF ( $\Delta H_f$ ) of 3,6-diazido-1,2,4,5-tetrazine, which was experimentally determined using an additive method, is the highest positive  $\Delta H_f$  compared to all other organic molecules [1282]. The calculated  $\Delta H_f$  of 3,6-diazido-1,2,4,5-tetrazine is +1101 kJ/mol. This is +91.75 kJ/atom, which is the highest positive  $\Delta H_f$  reported for all known organic molecules. Notably, the replacement of the first N<sub>3</sub> increases  $\Delta H_f$  by 19.21 kJ/atom, while the second N<sub>3</sub> increases  $\Delta H_f$  by an additional 54.45 kJ/atom. The unexpected azido-tetrazolo isomerizations and irreversible tetrazolo transformation of DiAT are remarkable compared to all other polyazido heteroaromatic high-nitrogen C—N compounds; e.g., 2,4,6-triazido-1,3,5-triazine; 4,4',6,6'-tetra(azido)hydrazo-1,3,5-triazine; 4,4',6,6'-tetra(azido)azo-1,3,5-triazine; and 2,5,8-tri(azido)-1,3,4,6,7,9b-heptaazaphenylene (heptazine).

3,6-Diazido-1,2,4,5-tetrazine has been synthesized from 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine by hydrazinolysis and diazotization [1321]. The molecular geometries, IR spectra, and thermodynamic properties were calculated using the DFT method. Contrary to observations by other investigators, Li et al [1321]. claim that IR spectra indicates that no azido-tetrazole tautomerism exists in solid DiAT. The thermodynamic parameters including heat capacities, entropies, and enthalpies were calculated according to IR spectra. The polynomial functions between thermodynamic parameters and temperature were determined also. The accurate enthalpy of formation of 1088 kJ/mol of DiAT in the gas phase was obtained via designed isodesmic reactions in which the tetrazine ring and the azide group have been kept intact. The data obtained from that study detailed a predicted detonation performance, with a detonation velocity of 8.45 km/s and detonation pressure of 31.3 GPa, both of which were higher than those of TNT and HMX counterparts. 3,6-diazido-1,2,4,5-tetrazine (DiAT) has the highest HOF (+966 kJ/mol = +231 kcal/mol) in comparison to those of DHT or DAAT.

The tautomerizations of polyazido-azine (ring-closure reaction) for 3,6-diazido-1,2,4,5-tetrazine (DiAT) and 2,4,6-triazido-1,3,5-triazine (TAT) were investigated by DFT methods [1322]. Enthalpies of formation were derived via isodesmic reactions. The changes of energies, geometries, and enthalpies of formation in the tautomerization showed that the enthalpies of formation increase in the process of cyclization, which makes this reaction less likely. The ring-closure reaction of TAT is thermodynamically more unfavorable in comparison to that of DiAT.

3,6-Bis(3,5-dimethylpyrazol-1-yl)1,2,4,5-tetrazine (BDT) was synthesized from guanidine nitrate, hydrazine hydrate, and acetylacetone as starting materials. Several high-nitrogen energetic compounds including 3-hydrazino-6-(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, 3-azido-6-(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, 3,6-di-hydrazino-1,2,4,5-tetrazine, 3,6-diazido-1,2,4,5-tetrazine, and 3,6-diguanidino-1,2,4,5-

tetrazine were synthesized by nucleophilic substitution reactions using BDT as a precursor and their structures were characterized by IR, MS, and NMR [1323].

The azido group attached to an aromatic heterocyclic ring can cyclize and isomerize to form a tetrazole fused ring. This does not happen with all azido groups attached to a ring; certain conditions must be met. The azido-tetrazole isomerization has caught many early investigators by surprise.

The azide-tetrazole isomerism in some diazido-1,2,4,5-tetrazines was investigated by *ab initio* quantum chemical methods to determine whether the polyazides are suitable starting materials for the synthesis of the isomeric tetrazoles [1250]. In the gas phase, polyazidoheterocycles do not cyclize to form tetrazoles. An electron-donating amino group favors the ring closure to tetrazoles, whereas an electron-withdrawing nitro group favors the linear azides. Solvation in polar solvents favors the formation of a tetrazole ring system due to higher charge separation in the tetrazole ring system. Diazidoazo- and hydrazotetrazines will readily cyclize to the tetrazoles in polar solvents.

A computational chemistry method was applied to study the molecular structures, electronic structures, and azido-tetrazole isomerization of azido-tetrazines [1324]. The results revealed that the reaction proceeds initially through the loss of the linearity of the azido group, with the terminal nitrogen N9 atom of the azide group approaching the nitrogen atom N2 of the ring. This step is followed by the attachment of the lone pair on N2 to the azido group, leading to the formation of the bond between N2 and N9. The bending of the N—N—N angle in the azido and the redistribution of electron density associated with these events gives rise to a large activation energy for the reaction.

The azido-tetrazolo tautomerization of 3,6-diazido-1,2,4,5-tetrazine (DiAT) in different solvents was investigated with HPLC and  $^{13}\text{C}$  NMR spectroscopy [1325]. The bicyclic compound 6-amino-tetrazolo[1,5-b]-1,2,4,5-tetrazine (ATTZ) was irreversibly formed as the final product by azido-cyclization following  $\text{N}_2$  elimination from one of the azido substituents at room temperature in DMSO. The structure of ATTZ was characterized by XRD, DSC, mass spectrometry, IR spectroscopy, and  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR spectroscopy. The crystal density was  $1.272\text{ g/cm}^3$ . The DSC result suggested that ATTZ with an m.p. of 357 K (84 °C) decomposed violently with explosion at 471 K (198 °C). It is so shock-sensitive that it can be regarded as a primary explosive.

DFT calculations were performed to study the molecular structures, HOFs, infrared spectra, detonation properties, and thermodynamic properties for five energetic 1,2,4,5-tetrazine derivatives [1326]. The results showed that 3,6-diazido-1,2,4,5-tetrazine is a promising candidate among HEDMs. NBO analysis indicated that the tetrazine compounds all have higher BDE when compared with RDX or HMX.

AIMD quantum chemical calculations were performed to study the thermal decomposition of isolated and crystal 3,6-diazido-1,2,4,5-tetrazine (DiAT) [1327]. During unimolecular decomposition, the three different initiation mechanisms predicted by the computer were N—N $\equiv$ N cleavage, ring-opening, and isomerization. The preferen-

tial initial decomposition step was the homolysis of the  $\text{N}-\text{N}\equiv\text{N}$  bond in the azido group. The release mechanisms of nitrogen gas were found to be very different in the early and later decomposition stages of crystal DiAT. In the early stages of decomposition, DiAT decomposed very quickly and drastically without forming any stable long-chains or heterocyclic clusters, and most of the nitrogen was released through the rapid rupture of nitrogen-nitrogen and carbon-nitrogen bonds. But in the later decomposition stages, the release of nitrogen gas was inhibited due to low mobility, long distances (from each other), and strong carbon-nitrogen bonds.

#### 20.4.4 Nitrotetrazines

Nitrotetrazines are multi-purpose energetic materials. In this group, there are examples for all classes of explosives: primary explosives, IHE, and gas generants. Starting with 3,6-diamino-1,2,4,5-tetrazine, three compounds of differing explosive behavior were prepared [303]. Physical data and small-scale explosive properties of the new substances were summarized in this publication.

To evaluate 3,6-dinitro-1,2,4,5-tetrazine (DNTAz), the geometries of this and two other compounds have been fully optimized using the DFT method [1221]. The accurate gas phase enthalpies of formation were obtained by using the atomization procedure and designing isodesmic reactions in which the parent rings are not destroyed. Based on calculated geometries and natural charges, the crystal structures have been predicted. Computed results revealed that extended conjugation exists over the parent rings of these compounds. More energy content was reserved in DNTAz than in other compounds investigated. The compounds were much more sensitive than 1,3,5-trinitrobenzene. The calculated detonation velocity of DNTAz reached 9.73–9.88 km/s, which is larger than that of CL-20.

The geometrical structures, NBOs, and enthalpies of formation of 23 different 1,2,4,5-tetrazine derivatives, including 3,6-dinitro-1,2,4,5-tetrazine, were calculated using theoretical MO methods. The predicted detonation properties (detonation velocity and detonation pressure) of the derivatives were estimated using the K-J equation [1328]. The predicted detonation velocities of these compounds were between 6.69 and 9.37 km/s. 3,6-Dinitro-1,2,4,5-tetrazine was one of the best performing explosives among the compounds studied. 3,6-Dinitro-1,2,4,5-tetrazine (DNTAz) has a density of  $\rho = 1.874\text{--}1.920\text{ g/cm}^3$ , a HOF  $\Delta H_f$  of +251 kJ/mol (+60 kcal/mol = +350 kcal/kg), and a predicted detonation velocity of  $D = 9730\text{--}9880\text{ m/s}$  [1299].

#### 20.4.5 Nitroalkyltetrazines

The DFT method was used to study the HOFs, energetic properties, and thermal stability for a series of trinitromethyl-substituted and tetrazine derivatives with different substituents [801]. It was found that the  $-\text{NO}_2$ ,  $-\text{NHNO}_2$ , or  $-\text{NF}_2$  groups play a very important role in increasing the HOFs of the derivatives. The calculated detonation velocities and pressures indicated that the group  $-\text{CF}_2\text{NF}_2$ ,  $-\text{NHNO}_2$ ,  $-1H$ -tetrazolyl,

–2*H*-tetrazolyl, or –1,2,4,5-tetrazinyl are effective structural units for enhancing the detonation performance of the rings they are attached to. An analysis of the BDE for several relatively weak bonds indicated that incorporating the –NHNO<sub>2</sub> and –NH<sub>2</sub> group into the parent ring decreased their thermal stability. Taking detonation performances and thermal stability into account, 37 compounds in this study could be considered as potential high-energy compounds. Their oxygen balances were close to zero.

Combining oxygen-rich trinitroethyl groups with diaminotetrazine resulted in energetic compounds like 3,6-bis(trinitroethylamino)tetrazine (BTAT, BiTNEAT), which has an enthalpy of formation of +336 kJ/mol, a density of 1.886 g/cm<sup>3</sup>, a detonation velocity of 9261 m/s, and an impact sensitivity of 7 J [876]. The onset of exotherm in the DSC is only at 457 K (184 °C), which gives it good thermal stability.

Some of the most promising candidates for high-nitrogen compounds are the neutral compounds, N<sub>3</sub>,N<sub>6</sub>-bis-(2,2,2-trinitroethyl)-1,2,3,4-tetrazine-3,6-diamine (BiTNEAT), and the two promising ionic compounds triaminoguanidinium dinitramide (TAG-DN), triaminoguanidinium 1-methyl-5-nitriminotetrazolate (TAG-1-MeAtNO<sub>2</sub>), 5-nitriminotetrazole (H<sub>2</sub>AtNO<sub>2</sub>), and 5-aminotetrazolium dinitramide [840, 841].

#### 20.4.6 Nitroaminotetrazines (Nitraminotetrazines)

The synthesis and properties of several new high-nitrogen materials with 3-amino-6-nitroamino-tetrazine (ANAT) as the anion were synthesized and characterized by IR and NMR spectroscopy and elemental analysis [1329]. One of the most energetic examples was the dianion salt of 3,6-diguanidyl-1,2,4,5-tetrazine with two 3-amino-6-nitroamino-tetrazinate anions with an enthalpy of formation of +1088.8 kJ/mol.

3-Amino-6-nitroamino-tetrazinate salt

3-Amino-6-nitroamino-tetrazine, *N*-nitro-3,6-diamino-1,2,4,5-tetrazine,  $C_2H_3N_7O_2$ ,  $M = 157.09$  g/mol, ANAT, has very attractive energetic properties. 3-Amino-6-nitroamino-tetrazine has a density of  $\rho = 1.71$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_{\text{ign}}$  of 437 K (164 °C), a HOF  $\Delta H_f$  of +464 kJ/mol (+111 kcal/mol = +707 kcal/kg), and a detonation velocity of  $D = 8230$  m/s. In nitramines, the nitroamino group plays an important role because of the presence of an energetic site and an acidic proton, thus making it possible for nitroamino-containing compounds to form corresponding salts. The nitramino group substantially improves the oxygen balance of the corresponding derivatives and eventually results in a higher exothermicity of combustion and detonation processes. The syntheses of the nitrogen-containing cation 3-amino-6-nitroamino-tetrazinate salts were easily accomplished by reacting ANAT with one equivalent of guanidine carbonate, aminoguanidine bicarbonate, 3,6-diguanidine tetrazine, aqueous ammonia, or its silver salt with diaminoguanidine chloride or triaminoguanidine chloride [202]. All of the salts were recovered as highly crystalline materials with excellent yields and purities. DSC and TGA studies revealed a family of very stable salts that decomposed exothermically upon melting. All of the salts had relatively high melting points for simple heterocyclic salts. This most likely can be attributed to the high basicity of guanidine or ammonia as well as the extent of the crystalline phase hydrogen bonding. The HOFs, detonation pressures, and detonation velocities were calculated and are summarized in Table 76.

The calculated enthalpies of formation for 3,6-diguanidine tetrazine nitrate (**No. 172**) and 3,6-diguanidine tetrazine perchlorate (**No. 173**) were in good agreement with the experimental values of −255 kJ/mol and the estimated value of −125 kJ/mol, respectively. This is impressive considering that the enthalpy of formation of 3,6-diguanidine tetrazine itself is reported to be +197 kJ/mol, which is a clear indication of the degree of energy.

*N,N'*-Dinitro-3,6-diamino-1,2,4,5-tetrazine, 3,6-dinitroamino-1,2,4,5-tetrazine, *N*-(6-nitramido-1,2,4,5-tetrazin-3-yl)nitramide,  $C_2H_2N_8O_4$ ,  $M = 202.09$  g/mol, has a density of  $\rho = 1.83$  g/cm<sup>3</sup>, an auto-ignition temperature of  $T_{\text{ign}}$  of 383 K (110 °C), an enthalpy of formation  $\Delta H_f$  of +565 kJ/mol (+135 kcal/mol) = 670 kcal/kg, and a detonation velocity of  $D = 8890$  m/s at a packing density of 1.71 g/cm<sup>3</sup>.

*N,N'*-Dinitro-3,6-diamino-1,2,4,5-tetrazine

The extent of nitration of *N,N'*-dialkyl-1,2,4,5-tetrazine-3,6-diamines under acidic conditions depends on the concentration of nitric acid and the selection of the alkyl sub-

**Table 76:** Structure and properties of energetic salts with 3-amino-6-nitroamino-tetrazinate (ANAT) anion.

| Compound No. | Compound name                                                | $T_{\text{dec}}$ onset of decomposition |       | Density<br>g/cm <sup>3</sup> | $H_L^a$<br>kJ/mol | $H_{fm}^b$<br>kJ/mol | $P_{\text{det}}$<br>GPa | $v_{\text{det}}$<br>m/s |

stituents at the exocyclic nitrogen atom [1330]. For instance, treating bis(alkylamino)-1,2,4,5-tetrazine with 98% HNO<sub>3</sub> produces the bis-alkylnitramino-1,2,4,5-tetrazine.

#### 20.4.7 Guanyltetrazines (Guanidinetetrazines)

3,6-Diguanidino-1,2,4,5-tetrazine, also known as; guanidine, *N,N'''*-1,2,4,5-tetrazine-3,6-diylbis-; *N,N'''*-1,2,4,5-tetrazine-3,6-diylbis[guanidine], 3,6-guanyl-*s*-tetrazine, bis(guanidinyl)tetrazine, 1-(6-guanidino-1,2,4,5-tetrazin-3-yl)guanidine, 1,1'-(1,2,4,5-tetrazine-3,6-diyl)diguanidine, 3,6-diguanidino-1,2,4,5-tetrazine, BGTz, C<sub>4</sub>H<sub>8</sub>N<sub>10</sub>, CAS RN [757961-08-3], *M* = 196.17 g/mol, can be converted to nitrate and perchlorate salts and to *N*-oxides. The guanidines are attached to the tetrazine ring at their 1-position

(end position) nitrogen and not at the 2-position (center position) nitrogen or the carbon atom.

3,6-Diguanidino-1,2,4,5-tetrazine

The nitrate and perchlorate salts of 3,6-diguanidino-1,2,4,5-tetrazine, as well as the nitrate and perchlorate salts of 3,6-diguanidino-1,2,4,5-tetrazine-1,4-di-*N*-oxide, 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylamino)-1,2,4,5-tetrazine and its 1,4-di-*N*-oxide derivative, 3,3'-azobis(6-amino-1,2,4,5-tetrazine), provide high-energy materials and high-nitrogen compounds with attractive properties [1331]. The dinitrate salt of bis(guanidiny)tetrazine, BGTz-DN; BGTz-2HNO<sub>3</sub>, C<sub>4</sub>H<sub>10</sub>N<sub>12</sub>O<sub>6</sub>, CAS RN [757961-10-7], *M* = 322.199 g/mol, has a density of 1.72 g/cm<sup>3</sup> and an enthalpy of formation of -196.6 kJ/mol (-47.0 kcal/mol = -146 cal/g). It contains 52.17% nitrogen and has an oxygen balance of -34.8%. Other sources reported the properties of the dinitrate salt as density  $\rho = 1.72$  g/cm<sup>3</sup>, auto-ignition temperature  $T_{\text{ign}} = 527$  K (254 °C), enthalpy of formation  $\Delta H_f = -225$  kJ/mol (-53.8 kcal/mol), and detonation velocity  $D = 7310$  m/s at a packing density of 1.6 g/cm<sup>3</sup>. The diperchlorate salt of BGTz has a density of  $\rho = 1.977$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_{\text{ign}}$  of 561 K (288 °C), an enthalpy of formation of  $\Delta H_f = -125.5$  kJ/mol (-30 kcal/mol), and a detonation velocity of  $D = 8070$  m/s at a packing density of 1.79 g/cm<sup>3</sup>.

3,6-Diguanidino-1,2,4,5-tetrazine (BDT) can be prepared by reaction of triamino-guanidinium nitrate with 2,4-pentanedione after condensation, oxidation, and neutralization [1332]. Using CH<sub>3</sub>COOH/NaNO<sub>2</sub> as the oxidizer and ethanol as the reactive medium, BDT was obtained with a yield of 85% at room temperature. This improvement reduced the cost of synthesis, raised the yield, and facilitated the experimental operation. Structures of BDT and its salts were confirmed by IR and NMR and thermal stability was measured by DSC.

3,6-Diguanidino-1,2,4,5-tetrazine dihydrate [(DGTz)(H<sub>2</sub>O)<sub>2</sub>] and its diperchlorate [(DGTz)(ClO<sub>4</sub>)<sub>2</sub>] were prepared and characterized by elemental analysis, FTIR, and XRD [1333]. The hydrogen atoms in the 3- and 6-positions of the tetrazine ring were substituted by two guanidino groups for (DGTz)(H<sub>2</sub>O)<sub>2</sub>, and two crystal water molecules were placed in the hydrate sphere. (DGTz)(H<sub>2</sub>O)<sub>2</sub> crystallized in the shape of monoclinic crystals, space group *C2/c*, with unit cell parameters of  $a = 1.3077$  nm,  $b = 0.36935$  nm,  $c = 1.9823$  nm,  $\beta = 95.158^\circ$ ,  $V = 0.9536$  nm<sup>3</sup>,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.618$  g/cm<sup>3</sup>. In the (DGTz)(ClO<sub>4</sub>)<sub>2</sub> crystal, two ClO<sub>4</sub><sup>-</sup> anions and one DGTz<sup>2+</sup>

cation were bonded together by electrostatic attraction and hydrogen bonds. The (DGTz)(ClO<sub>4</sub>)<sub>2</sub> crystals crystallized in the shape of monoclinic crystals, space group *P*2<sub>1</sub>/*c*, with unit cell parameters of *a* = 0.48581 nm, *b* = 1.3058 nm, *c* = 1.0519 nm, *β* = 91.159°, *V* = 0.6672 nm<sup>3</sup>, *Z* = 2, and *ρ*<sub>XRD</sub> = 1.977 g/cm<sup>3</sup>. The thermal decomposition process of the two compounds was investigated by DSC and TGA-DTG and the activation energy was derived. In the DTA-DSC with a heating rate of 10°/min, (DGTz)(H<sub>2</sub>O)<sub>2</sub> begins to lose water at 54 to 98 °C with a peak at 79 °C (endotherm). This is followed by a sharp exotherm starting at 273 °C that maxes at 297 °C. (DGTz)(ClO<sub>4</sub>)<sub>2</sub> decomposed directly without melting. In the DSC curve of (DGTz)(ClO<sub>4</sub>)<sub>2</sub>, there is only one sharp exotherm starting at 255.7 °C that maxes at 272.4 °C. The apparent activation energy of (DGTz)(H<sub>2</sub>O)<sub>2</sub> decomposition was 228.6 kJ/mol which was about 50 kJ/mol higher than the apparent activation energy of (DGTz)(ClO<sub>4</sub>)<sub>2</sub>, which was only 178.5 kJ/mol.

The molecular structures of three stable conformations of salts formed from 3,6-diguanidino-1,2,4,5-tetrazine-1,4-di-*N*-oxide (DTDO) and HNO<sub>3</sub> and HN(NO<sub>2</sub>)<sub>2</sub> were calculated using DFT methods and free energies. The total energies of the three conformations were compared to hydrogen bonding interaction, charge transfer, binding energy, dispersion energy, and the second-order perturbation energy [1334]. Aromaticities of tetrazine in different conformations were slightly different. Although the stabilities of the three conformations are different, their values were comparable.

The strand burning rates of 3,6-diguanidino-1,2,4,5-tetrazinium nitrate (DGTN) and TAGN, their combustion wave structure, and the location and chemical nature of the leading reaction of combustion were determined and compared to each other [1335]. Burning rate measurements were carried out in a windowed 1.5-L constant-pressure bomb. The mixtures under investigation were placed in transparent acrylic tubes that were 7 mm in diameter and 12–15 mm long. Temperature profiles in the combustion wave were measured using thin tungsten-rhenium thermocouples. DGTN in the form of samples pressed into acrylic tubes can even sustain stable combustion at sub-atmospheric pressures. In the pressure range of 0.1–10 MPa, DGTN burns 1.5–2 times faster than HMX but 2–3 times slower than TAGN. The surface temperatures in the combustion of TAGN and DGTN are very close and are controlled by a dissociation process, just as they are for other onium salts,. The burning rates of both substances are governed by processes in the condensed phase.

3,6-Diguanidino-1,2,4,5-tetrazinium dinitroguanidinate salt can be prepared in 82.2% yield by using hydrazine hydrate, guanidinium nitrate, and nitroguanidine as raw materials under optimum synthetic conditions (reaction time and reaction temperature of 323 K/50 °C) [1336]. The thermal decomposition behavior was studied by DSC and TGA-DTG and its detonation properties were predicted using DFT methods. The compound decomposed at about 533 K (260 °C), demonstrating good thermal stability. The HOF of the compound obtained by Born-Haber cycle was 294.9 kJ/mol. The theoretical density predicted by a Monte-Carlo method was 1.69 g/cm<sup>3</sup>. The

predicted detonation velocity and detonation pressure calculated by the K-J equation were 7.67 km/s and 25.04 GPa, respectively.

#### 20.4.8 Nitroguanyltetrazines (Nitroguanidinotetrazines)

3,6-Diguanidino-1,2,4,5-tetrazine has served as an ingredient in several of the energetic materials already described in this chapter. Now, instead of just two plain guanidino groups attached to tetrazine, a more energetic compound can be made by attaching two nitroguanidino groups to tetrazine. This compound is no longer a base; it is an acid that can form salts with a variety of bases. 3,6-Bis(nitroguanidinyl)-1,2,4,5-tetrazine; guanidine, *N,N'*-1,2,4,5-tetrazine-3,6-diylbis[*N*-nitro-]; 1-nitro-3-[6-[(*N*-nitrocarbamimidoyl)amino]-1,2,4,5-tetrazin-3-yl]guanidine, (NQ)2Tz, NQ2Tz, DNGTz, CAS RN [756482-91-4],  $C_4H_6N_{12}O_4$ ,  $M = 286.168$  g/mol, melts at 501 K (228 °C) (decomp.) and has a density of 1.76 g/cm<sup>3</sup>. It is an energetic material. The enthalpy of formation is +389 kJ/mol (+93.0 kcal/mol = +325 cal/g). It contains 58.73% nitrogen and its oxygen balance is -39.1%.

3,6-Bis(nitroguanidinyl)-1,2,4,5-tetrazine

3,6-Bis(nitroguanidinyl)-1,2,4,5-tetrazine is a dibasic acid and forms salts with a variety of bases. The triaminoguanidinium salt of 3,6-bis(nitroguanidinyl)-1,2,4,5-tetrazine, also known as (TAG)2(NQ)2Tz, CAS RN [756482-94-7],  $C_6H_{22}N_{24}O_4$ ,  $M = 494.41$  g/mol, has a density of 1.610 g/cm<sup>3</sup>. Chemical Abstracts lists this compound as “3,6-bis(nitroguanidinyl)-1,2,4,5-tetrazine, bis(triaminoguanidinium) salt” or “carbonohydrazonic dihydrazide, compound with *N,N'*-1,2,4,5-tetrazine-3,6-diylbis-(*N'*-nitroguanidine) (2:1).” It is a high-nitrogen content (68% N) energetic material that melts at 439 K (166 °C) and has an enthalpy of formation of +1255 kJ/mol (+300 kcal/mol = +607 cal/g). Other literature sources gave the enthalpy of formation of (TAG)2(NQ)2Tz as  $\Delta H_f = +711$  kJ/mol (+170 kcal/mol = +345 kcal/kg).

Another salt formed with 3,6-bis(nitroguanidinyl)-1,2,4,5-tetrazine is the bis-(1-methyl-4,5-diaminotetrazolium) salt, (MAT)2(NQ)2Tz, with a molecular mass of 514.4 g/mol, but only a few properties are known. There are no known applications of this compound.

The synthesis of several high-nitrogen materials based on nitroguanyl-substituted tetrazines by reaction of tetrazine derivatives with the anion of nitroguanidine

(anionic heteroatom nucleophile) in the first stage led to a bis(nitroguanidiny)-tetrazine disodium salt that was prepared from 3,6-bis(3,5-dimethyl-1*H*-pyrazol-1-yl)-1,2,4,5-tetrazine and nitroguanidine sodium salt (formed *in-situ*) [1337]. Treatment of this disodium salt with triaminoguanidinium hydrochloride produced a bis-(triaminoguanidinium) salt. Gas pycnometry of the triaminoguanidinium salt of 3,6-bis(nitroguanidiny)-1,2,4,5-tetrazine indicated a crystal density near 1.61 g/cm<sup>3</sup>. The HOFs were determined to be +1255 kJ/mol (+300 kcal/mol), making them an attractive candidate for energetic materials applications.

3,6-Bis-nitroguanyl-1,2,4,5-tetrazine (NQ2Tz) and its bis-triaminoguanidinium salt (TAG)2(NQ)2Tz exhibited very low pressure dependence in burning rate [1338]. Flash pyrolysis/FTIR spectroscopy provided some insight into this interesting burning behavior.

The reaction between acetyl acetone and TAGN at 343–348 K (70–75 °C) produced 1,3,6-bis-(3,5-bismethyl-pyrazole-*N*-yl)-1,2-dihydro-*s*-tetrazine; at 313–318 K (40–45 °C) it produced 2,α,α'-bis(3,5-bismethyl-pyrazole-*N*-yl)-carbene-acetyl-isopropenyl hydrazine [1339]. They were characterized by IR, MS and <sup>1</sup>H-NMR spectra, and XRD. The results of crystal structure determination showed that there exist intermolecular hydrogen bonds which stabilize the crystals.

TGA-FTIR was used in real-time to measure the thermal decomposition behavior of 3,6-bis-nitroguanyl-*s*-tetrazine dihydrate (DNGTz•2H<sub>2</sub>O) with constant rate-controlled heating (10 °C/min) [1340]. The thermal decomposition of DNGTz•2H<sub>2</sub>O can be divided into three stages. The first stage was an endothermic process with a mass loss of 10% for the loss of two molecules of water. The second stage was an exothermic stage that took place between 501 and 526 K (228 and 253 °C) with a mass loss of 68.66%. The third stage happened between 734 and 846 K (461 and 573 °C) with a mass loss of 17.46%. The FTIR spectra showed that the main products of the thermal decomposition of DNGTz•2H<sub>2</sub>O were NO<sub>2</sub>, N<sub>2</sub>O, NH<sub>3</sub>, CO<sub>2</sub>, and N<sub>2</sub>.

3,6-Dinitroguanidino-1,2,4,5-tetrazine (DNGTz) was synthesized with a yield of 92.3% from 3,6-bis(3,5-dimethylpyrazole-1-yl)-1,2-dihydro-1,2,4,5-tetrazine through oxidation and substitution [1341]. The bis(triaminoguanidinium) salt of 3,6-dinitroguanidino-1,2,4,5-tetrazine (TGA-DNGTz) and a bisguanylylurinium salt of 3,6-dinitroguanidino-1,2,4,5-tetrazine (M-DNGTz) were synthesized and their structures were characterized by FTIR, <sup>1</sup>H NMR, <sup>13</sup>C NMR, and elemental analysis. The conditions for the reactions of oxidation and substitution were optimized. The physico-chemical properties, detonation, and thermal stability of DNGTz, TGA-DNGTz, and M-DNGTz were measured. Their decomposition temperatures were 491.8, 463.3, and 476.8 K (218.7, 190.2, and 203.7 °C), respectively.

From the viewpoint of designing high-performance energetic materials, the most widely used strategy is to incorporate some energy-containing groups such as nitro, azido, azo, or *N*-oxide into the molecular backbone of the high-nitrogen heterocycles (especially the 1,3,5-triazine or 1,2,4,5-tetrazine ring). Nitroguanidyl-functional-

ized nitrogen-rich materials derived from 1,3,5-triazine and 1,2,4,5-tetrazine were synthesized through reactions between *N*-nitroso-*N'*-alkylguanidines and the hydrazine derivatives of 1,3,5-triazine or 1,2,4,5-tetrazine and were characterized by NMR and IR spectroscopy, elemental analysis, and DSC [1266]. The HOFs for all compounds were calculated and then combined with experimentally determined densities to calculate the predicted detonation pressures and velocities.

3,6-Bis-nitroguanyl-1,2,4,5-tetrazine (DNGTz) was synthesized by a similar method and its thermal behavior was studied by DSC and TGA-DTG [1342]. The DSC data were used to analyze the thermal decomposition mechanism and kinetics using the methods of Kissinger, Ozawa, and integral. The thermal kinetic parameters of the activation energy and pre-exponential factor were  $E_a = 187.23 \text{ kJ/mol}$  and  $A = 10^{15.01} \text{ s}^{-1}$ , respectively. The thermal safety of DNGTz and the density ( $\rho = 1.762 \text{ g/cm}^3$ ) and thermal conductivity ( $\lambda = 0.1856 \text{ W m}^{-1} \text{ K}^{-1}$ ) were estimated and the specific heat capacity ( $c_p$ ) was measured in a micro-calorimeter to obtain the dependence of  $c_p$  on  $T$  for the range  $287 \text{ K} < T < 352 \text{ K}$

$$c_p = -2.8805 + 2.1283 \times 10^{-2}T - 2.3132 \times 10^{-5}T^2 - 1.1689 \times 10^{-8}T^3$$

where  $c_p$  is the heat capacity in  $\text{J g}^{-1} \text{ K}^{-1}$  and  $T$  is the temperature in kelvin. The thermal decomposition kinetic parameters, mechanism function, and the equations of  $c_p$ ,  $\rho$ , and  $\lambda$  were combined to evaluate thermal stability of DNGTz. The adiabatic-time-to-explosion was 8.16 s. The self-accelerating decomposition temperature was  $T_{\text{SADT}} = 522.2 \text{ K} = 249.12^\circ\text{C}$ . The thermal ignition temperature was  $T_{\text{be}} = 535.4 \text{ K} = 262.3^\circ\text{C}$ . The critical temperature of thermal explosion was  $T_{\text{bp}} = 484.8 \text{ K} = 211.7^\circ\text{C}$ . The thermal sensitivity probability density function  $S(T)$  vs  $T$  for DNGTz was calculated for different geometries, including infinite cylindrical, spheroidal, or infinite platelike shapes with a radius of 1 m. The thermal safety of the spheroidal geometry was found to be better than that of the infinite cylindrical or infinite platelike geometry.

More recent literature sources gave the following properties for 3,6-bis-(nitroguanidinyl)-1,2,4,5-tetrazine (NQ2Tz): density  $\rho = 1.76 \text{ g/cm}^3$ , auto-ignition temperature  $T_{\text{ign}} = 501 \text{ K}$  ( $228^\circ\text{C}$ ), HOF  $\Delta H_f = +389 \text{ kJ/mol}$  ( $+93 \text{ kcal/mol} = +330 \text{ kcal/kg}$ ), and detonation velocity  $D = 7840 \text{ m/s}$  at a packing density of  $1.7 \text{ g/cm}^3$ , vapor pressure

$$\ln p = 30.4 - 22540/T$$

where  $p$  is the vapor pressure in atm and  $T$  is the temperature in kelvin [1299]. 3,6-Bis-(nitroguanidinyl)-1,2,4,5-tetrazine can burn at very low pressures. The strand burning rate for pressures between 0.02 and 10 MPa follows the equation

$$r_b = 5.04p^{0.42}$$

where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in MPa. NQ2Tz burning rate is very sensitive to impurities. This substance can burn at sub-atmospheric pressure. There is flameless combustion at low pressures and a luminous flame appears above 2 MPa. The strand burning rate of the triaminoguanidinium salt of NQ2Tz between 0.1 and 10 MPa can be expressed by the following equation:

$$r_b = 7.6p^{0.52}$$

where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in MPa.

#### 20.4.9 Other Di-Substituted Tetrazine Derivatives

The properties of 3,6-dihydrazino-1,2,4,5-tetrazine (DHT), 3,3'-azobis(6-amino-1,2,4,5-tetrazine) (DAAT), 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine (BTATz), and 5,5'-bitetrazole (BHT) were compared among the promising high-nitrogen energetic materials [1308, 1343]. Because of their highly positive HOFs and higher density, these high-nitrogen compounds are unique in their gas generating ability, having little or no smoke and a lack of residue. This makes them compounds of interest for applications in insensitive explosives, low signature propellants, gas generants, and low-smoke pyrotechnics. An excellent source of information on tetrazines as energetic materials is provided in [1299, 1344], with lecture slides accompanying one of the book chapters.

### 20.5 C—C-Linked, C-Bridged, and Fused Multi-Ringed Tetrazines

3,6-Bis-(3,5-dimethylpyrazol-1-yl)-*s*-tetrazine, 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, BDT,  $C_{12}H_{14}N_8$ ,  $M = 270.293$  g/mol, can be synthesized from triaminoguanidinium chloride and 2,4-pentanedione (= acetylacetone) followed by oxidation by atmospheric oxygen or nitrogen dioxide. Starting with the precursor 3,6-bis-(3,5-dimethylpyrazol-1-yl)-*s*-tetrazine (BDT), several useful energetic compounds based on the *s*-tetrazine system have been synthesized and studied [1345], including 3,6-diamino-*s*-tetrazine-1,4-dioxide (LAX-112), 3,6-bis-(1*H*-1,2,3,4-tetrazol-5-ylamino)-*s*-tetrazine, and 3,6-dihydrazino-*s*-tetrazine (DHT).

3,6-Bis-(3,5-dimethylpyrazol-1-yl)-s-tetrazine (BDT)

3,6-Bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine (BDT) was synthesized from guanidinium nitrate, hydrazine hydrate, and acetylacetone as starting materials [1323]. Several high-nitrogen energetic compounds, including 3-hydrazino-6-(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, 3-azido-6-(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine, 3,6-dihydrazino-1,2,4,5-tetrazine, 3,6-diazido-1,2,4,5-tetrazine, and 3,6-diguanidino-1,2,4,5-tetrazine, were synthesized by nucleophilic substitution reactions using BDT as a precursor. Their structures were characterized by IR, MS, and NMR.

3,6-Bis(3,5-dimethyl-1*H*-pyrazol-1-yl)-1,2-dihydro-1,2,4,5-tetrazine was synthesized from guanidine hydrochloride and acetylacetone by an amazing multiple ring-closure reaction [1346]. Three additional 1,2,4,5-tetrazine derivatives were synthesized, starting from 3,6-bis(3,5-dimethyl-1*H*-pyrazol-1-yl)-1,2-dihydro-1,2,4,5-tetrazine by oxidation and substitution. These compounds were characterized by  $^1\text{H}$  NMR and MS. The single-crystal XRD study of N3,N6-bis(pyridin-2-ylmethyl)-1,2,4,5-tetrazine-3,6-diamine indicated that it belongs to the triclinic system, space group  $P_1$ . The unit cell parameters were:  $a = 8.0764(16) \text{ \AA}$ ,  $b = 9.5262(19) \text{ \AA}$ ,  $c = 10.243(2) \text{ \AA}$ ,  $\alpha = 86.08(3)^\circ$ ,  $\beta = 74.60(3)^\circ$ ,  $\gamma = 69.87(3)^\circ$ ,  $V = 713.1(2) \text{ \AA}^3$ , and  $Z = 2$  [303]. Physical data and small-scale explosive properties of new triazole and tetrazine derivatives were summarized in this publication.

The enthalpy of formation of 3,6-bis(2*H*-tetrazol-5-yl)-1,2,4,5-tetrazine (BTT) is  $\Delta H_f^{298} = +933 \text{ kJ/mol} = +223 \text{ kcal/mol}$  [1347]. The thermal decomposition behavior of BTT and DAAT was thermo-analytically characterized. Both substances decomposed at surprisingly high temperatures of  $>473 \text{ K}$  ( $>200^\circ\text{C}$ ). The heats of decomposition released were among the highest ever measured for energetic materials under similar experimental conditions and were released over a relatively narrow temperature range. More recent sources of information listed the properties of BTT as  $\rho = 1.68 \text{ g/cm}^3$ , auto-ignition temperature  $T_i = 508 \text{ K} = 235^\circ\text{C}$ ,  $\Delta H_f = +937 \text{ kJ/mol} = +224 \text{ kcal/mol} = +1026 \text{ kcal/kg}$  [1299].

The enthalpy of formation, theoretical crystal density, and explosive performance of *s*-tetrazine derivatives, in which two different  $\text{O}_2\text{N}$ -,  $\text{H}_2\text{N}$ -, and  $\text{N}_3$ -substituted imidazoles, triazoles, or tetrazoles were attached to the tetrazine ring in the 3- and 6-positions, were calculated using DFT methods [1348]. The predicted results showed that azide groups increase all enthalpy of formation values of the *s*-tetrazine derivatives. The densities for the designed molecules were predicted by using crystal packing calculations. The introduction of  $-\text{NO}_2$  groups improved the density and, hence, the detonation performance was better than the  $-\text{N}_3$  or  $-\text{NH}_2$  groups. Amino derivatives are better candidates based on their insensitivity and thermal stability.

The reaction of hydrazine with the lowest member of the aldehyde family, formaldehyde, proceeds quite unexpectedly beyond the hydrazone, and results in the formation of tetraformaltrisazine, 1,2,3,4,6,7,8,9-octahydro-[1,2,4,5]tetrazino-[1,2-*a*][1,2,4,5]tetrazine, TFTA,  $\text{C}_4\text{H}_{12}\text{N}_6$ ,  $M = 144.18 \text{ g/mol}$ , CAS RN [1743-13-1], which is a white powder [1349, 1350].

Tetraformaltrisazine polymerizes after a few minutes with excess formaldehyde to form a white gelatinous precipitate. The precipitate forms even if formaldehyde is reacted with the azine formed by reactions of hydrazine with an excess of acetone. Formaldehyde reverses the acetone-hydrazine reaction. 2,3-Diazabuta-1,3-diene (formalazine)  $\text{H}_2\text{C}=\text{N}=\text{CH}_2$  cannot be isolated but polymerizes [1351, 1352].

The enthalpy of formation of tetraformaltrisazine is  $+475 \text{ kcal/100 g} = +475 \text{ cal/g} = +68.5 \text{ kcal/mol} = +286 \text{ kJ/mol}$ , which is derived from heat of combustion measurements. The pyrolysis and combustion of TFTA leads to much nitrogen, hydrogen, carbon dioxide, some carbon monoxide, and only a little methane and ethylene [1353, 1354]. This makes it a good source of nitrogen for gas generator propellants and for blowing agents that are used in making plastic foams. TFTA can also be used as the fuel for hybrid rockets [1355].

## 20.6 —N=N—Linked Azo-s-tetrazines

While azo-s-tetrazine may have a few desirable properties, continued synthesis efforts have yielded a derivative of azo-s-tetrazine, 3,3'-azobis(6-amino-s-tetrazine), or DAAT, which has a very high positive enthalpy of formation [1347]. As far as the nomenclature is concerned, the prefix “bis” appears to be unnecessary. For instance, “azobenzene” describes a molecule consisting of a diazene group with two phenyl rings, and the prefix “bis” is not used.

3,3'-Azobis(6-amino-1,2,4,5-tetrazine), 6,6'-(1E)-azobis-1,2,4,5-tetrazin-3-amine, diaminoazotetrazine, 6-[[*(Z)*-aminomethylazo]-[methylene-(methyleamino)-λ5-azanyl]-methyl]azo-1,2,4,5-tetrazin-3-amine, DAAT,  $C_4H_4N_{12}$ , CAS RN [286472-58-0],  $M = 220.16$  g/mol, is a very sensitive high-nitrogen compound. This is surprising because it does not contain any oxygen and has a very high density of  $1.840$  g/cm<sup>3</sup>. 3,3'-azobis-(6-amino-1,2,4,5-tetrazine) was prepared starting from 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine (DBT) [1356, 1357]. The energetic compound was characterized by spectroscopic methods, XRD, DSC, and combustion calorimetry. The pure material is thermally stable up to  $525$  K =  $252$  °C. The enthalpy of formation was measured to be  $+862$  kJ/mol ( $+206$  kcal/mol). The drop weight impact sensitivity value was  $70$  cm (for comparison, HMX is  $21$  cm) even though there are no oxygen atoms in the molecule. The compound is insensitive to initiation by spark ( $>0.36$  J) or friction (BAM  $>36$  kg) and the density was once reported as  $1.84$  g/cm<sup>3</sup>. However, later gas pycnometry measurements have placed the density more accurately at  $1.78$  g/cm<sup>3</sup>, which was very likely related to the densest C, H, N molecule known at that time [1358].

The properties of DAAT were compared to those of other energetic high-nitrogen compounds. These are leading candidates among other promising high-nitrogen energetic materials [1308, 1343]. Because of their highly positive HOFs and higher density, these high-nitrogen compounds are unique in their gas-generating abilities. They generate little to no smoke and lack any leftover residue.

3,3'-Azobis(6-amino-1,2,4,5-tetrazine) (DAAT) along with 3,3'-diamino-4,4'-azoxyfurazan (DAAF) and 1,4-dihydrazino tetrazine (DHTz) were synthesized and characterized by IR, NMR, MS, TG-DTA, DSC, TG-FTIR, and impact and friction sensitivity tests [682]. DAAF was insensitive to mechanical stimuli whereas DAAT and DHTz were vulnerable to impact stimuli. The theoretical explosive power of DAAF, DAAT, and DHTz alone and their combinations with well-known IHE as well as that of propellants based on them were calculated.

3,3'-Azobis(6-amino-1,2,4,5-tetrazine) (DAAT) can be synthesized from guanidinium nitrate and hydrazine hydrate via a seven-step reaction [1359]. The structure and composition were characterized by  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, IR, and elemental analysis [1360, 1361]. Other sources of properties of DAAT reported  $\rho = 1.78 \text{ g/cm}^3$ ; auto-ignition temperature  $T_i = 592 \text{ K} = 319^\circ\text{C}$ ;  $\Delta H_f = +862 \text{ kJ/mol} = +206 \text{ kcal/mol} = 936 \text{ kcal/kg}$ ; measured detonation velocity  $D = 7400 \text{ m/s}$  at a packing density of  $1.65 \text{ g/cm}^3$  [1299].

3,3'-Azobis(6-amino-1,2,4,5-tetrazine) (DAAT) was included in a demonstration of DFT calculations for a group of energetic materials and used to check the validity of calculations because it was one of the few molecules for which experimental data were available [1305]. This source reported the density of DAAT as  $1.76 \text{ g/cm}^3$  (which is similar to the density reported by other sources). The predicted HOF of DAAT vapor was  $+1146 \text{ kJ/mol}$  ( $+274 \text{ kcal/mol}$ ). The heat of sublimation of DAAT was measured to be  $167 \text{ kJ/mol}$  ( $40 \text{ kcal/mol}$ ). The measured enthalpy of formation of solid DAAT is  $+979 \text{ kJ/mol}$  ( $+234 \text{ kcal/mol}$ ). The predicted detonation velocity is  $D = 8250 \text{ m/s}$  and the predicted CJ pressure is  $P = 31.14 \text{ GPa}$ . In this work, the reference molecules DAAT and DHT were studied to validate the theoretical approach and to facilitate further progress toward the development of previously unknown molecules (some of which were to be obtained by forming *N*-oxides of DAAT). The DAAT oxidation will preferably take place at N1, N'1, N3, N'3, N5, and N'5 positions rather than N2, N'2, N4, or N'4.

Nitrogen-bridged 1,2,4,5-tetrazine-, furazan-, and 1*H*-tetrazole-based polyheterocyclic compounds were prepared and characterized by HOFs, thermal stability, and detonation properties [1104]. This included 3,6-bis(1*H*-1,2,3,4-tetrazole-5-ylamino)-1,2,4,5-tetrazine, 3,6-bis(furazan-5-ylamino)-1,2,4,5-tetrazine, 3,4-bis(1,2,4,5-tetrazine-3-ylamino)-furazan, and 1,5-bis(1,2,4,5-tetrazine-3-ylamino)-1*H*-1,2,3,4-tetrazole.

The fast and precise modeling of the enthalpy of formation and the density of the HEDMs would simplify the design and selection process of these materials. Seven recently synthesized 1,2,4-triazine-based compounds were modeled by computer [1362]. For the validation of the model, a well-characterized molecule (DAAT) that is similar to the seven other ones was selected as a benchmark for comparing predicted and experimentally measured properties.

## 20.7 Triazolotetrazines and Tetrazolotetrazines

Attaching additional fused rings to tetrazine created a new category of heterocyclic compounds. Five- or six-membered nitrogen-containing heterocycles are traditional sources of energetic materials. Triazole, tetrazole, and tetrazine derivatives have been investigated extensively as HEDMs, both theoretically and experimentally. The desired properties are high densities, high enthalpies of formation, and high thermal stability (due to aromaticity). Of course, increasing interest in the chemistry of 1,2,4,5-tetrazine derivatives has stimulated research on 1,2,4,5-tetrazine-based compounds.

Among them, 1,2,4-triazolo-[4,3-*b*]-1,2,4,5-tetrazine (TTZ) and its substituted derivatives have been synthesized and investigated.

1,2,4-Triazolo-[4,3-*b*]-1,2,4,5-tetrazine (TTZ)

The first synthesis of this ring system was reported in 1968 [1363]. Chavez and Hiskey [1288] synthesized the parent TTZ ring and obtained its mono-substituted and di-substituted derivatives: 6-amino-1,2,4-triazolo-[3,4-*b*]-1,2,4,5-tetrazine (ATTZ) and 3,6-diamino-1,2,4-triazolo-[3,4-*b*]-1,2,4,5-tetrazine (AATZ). The melting points of TTZ, ATTZ, and AATZ are 483, 490, and 605 K (210, 217, and 332°C), respectively. The parent tetrazolo-[1,5-*b*]-1,2,4,5-tetrazine (TETZ) ring was synthesized and its explosive properties were reported.

Tetrazolo-[1,5-*b*]-1,2,4,5-tetrazine (TETZ)

The friction and shock sensitivity of 6-diamino-tetrazolo-[1,5-*b*]-1,2,4,5-tetrazine (AATZ) were reported by [303]. One substituent can go into the 8-position in TETZ and one or two substituents can go into the 2- or 8-position in TTZ. A systematic design of TTZ- and TETZ-based more energetic compounds with higher performance and less sensitivity was supported by computational chemistry and a lot of imagination. The enthalpies of formation for a series of 40 different tetrazolo-[1,5-*b*]-1,2,4,5-tetrazine (TETZ) and 1,2,4-triazolo-[3,4-*b*]-1,2,4,5-tetrazine (TTZ) derivatives were calculated by using a DFT method [1364]. The results showed that the attachment of  $-N_3$  or  $-N(NO_2)_2$  groups on the TETZ or TTZ ring enhances their enthalpy values. In the case of mono-substituted derivatives, attachment of a substituent to the 8-position in the TETZ or TTZ ring will increase its energy gaps, although not for the derivatives with the  $-NO_2$  group. The substitution of the  $-NH_2$  group in the TETZ ring is favorable for enhancing its thermal stability. For the TTZ ring, different substituted positions and numbers of the substituent might affect its thermal stability. The calculated detonation properties indicated that incorporating the  $-NO_2$ ,  $-NF_2$ ,  $-ONO_2$ , or  $-N(NO_2)_2$  group into the TETZ or TTZ ring will enhance its detonation performance.

For the TETZ derivatives, the largest  $\rho$  value and the smallest were 1.96 and 1.68 g/cm<sup>3</sup>, respectively, whereas for the TTZ derivatives, the largest  $\rho$  value and the smallest were 2.05 and 1.60 g/cm<sup>3</sup>, respectively. Calculated BDE can be correlated to the thermal stability and impact sensitivity of these compounds. Calculated predicted explosive performance of 40 different compounds was compared to that of RDX and HMX calculated data, as reported in the literature.

6-Aminotetrazolo-[1,5-b]-1,2,4,5-tetrazine has a density of  $\rho = 1.68$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_i$  of 476 K (203 °C), a HOF of  $\Delta H_f = +611$  kJ/mol (+146 kcal/mol = 1060 kcal/kg), a detonation velocity of  $D = 7970$  m/s at a packing density of 1.6 g/cm<sup>3</sup>, and its sensitivity is similar to that of other primary explosives [1299]. 6-Aminotetrazolo-[1,5-b]-1,2,4,5-tetrazine is thermally less stable than the related 6-aminotriazolo-[1,5-b]-1,2,4,5-tetrazine. 6-Aminoguanidino-tetrazolo-[1,5-b]-1,2,4,5-tetrazine, 2-tetrazolo[1,5-b]-1,2,4,5-tetrazino-6-hydrazinecarboxamide, 2-tetrazolo[1,5-b]-1,2,4,5-tetrazinyl-6-hydrazinecarboxamide (STTZ) has a density of  $\rho = 1.84$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_{ign}$  of 488 K (215 °C), a HOF  $\Delta H_f$  of +477 kJ/mol (+114 kcal/mol = +584 kcal/kg) and a detonation velocity of  $D = 6080$  m/s at a packing density of 1.43 g/cm<sup>3</sup>. In the 2+1-ring structure of 6-(tetrazolyl-5-amino)-tetrazolo-tetrazine (TzATTz), the hydrogen atom at the —NH— bridge becomes acidic because electrons have been drained away from the bridge nitrogen into the adjacent aromatic ring structures.

6-(Tetrazolyl-5-amino)tetrazolo-tetrazine (TzATTz)

6-(Tetrazolyl-5-amino)tetrazolo-tetrazine, *N*-(1*H*-tetrazol-5-yl)tetrazolo[1,5-*b*][1,2,4,5]-tetrazin-6-amine, has a density of  $\rho = 1.98$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_{ign}$  of 461 K (188 °C), an enthalpy of formation  $\Delta H_f$  of 925 kJ/mol (221 kcal/mol = 1077 kcal/kg), and a detonation velocity of  $D = 7390$  m/s at a packing density of 1.52 g/cm<sup>3</sup>. The triaminoguanidinium salt of 6-(tetrazolyl-5-amino)tetrazolo-tetrazine has a density of  $\rho = 1.49$  g/cm<sup>3</sup>, an auto-ignition temperature  $T_{ign}$  of 460 K (187 °C), an enthalpy of formation  $\Delta H_f$  of +1092 kJ/mol (+261 kcal/mol = +845 kcal/kg), and a detonation velocity of  $D = 6800$  m/s at a packing density of 1.49 g/cm<sup>3</sup>.

Combustion behavior, flame structure, and thermal decomposition of fused-ring compounds based on tetrazine, triazole, and furazan rings have been described [1365]. It was found that the introduction of a [1,2,4]triazolo[3,4-*b*][1,2,4,5] tetrazine core into the multi-ringed structure of energetic molecules allows energetic compounds with combustion rates greater than those of HMX or RDX to be obtained. These compounds

Table 77: Summary of high nitrogen organic compounds and their properties.

have good thermal stability that depend on the substituent at the furazan ring (not on the triazolotetrazine core). The burning rates of nitrogen-rich compounds of this type are controlled by the decomposition kinetics at burning surface temperatures. The two-stage decomposition of these substances leads to the appearance of two regions in the burning rate-pressure dependency charts. These transition to each other through an instability region.

Nitrate ester derivatives of 1,2,4,5-tetrazine and 1,2,4-triazolo[3,4-b]-[1,2,4,5]-tetrazine ring systems had lower thermal stabilities relative to PETN, although they had slightly improved mechanical sensitivities [1366]. The presence of electron-rich amine donors leads to a cathodic shift of the tetrazine redox potentials, making them suitable as sensors for explosive vapor detectors.

Various high-nitrogen energetic materials, viz., dinitro-azo-triazole, triamino-guanidinium azotetrazolate (TAGAT), guanidinium azotetrazolate (GAT or GZT), bistetrazolylamino tetrazine (BTATz), dihydrazino tetrazine, bis(guanidinyl)tetrazine dinitrate, and diamino azobistetrazine *N*-oxide (DAAT-N-Ox) were investigated as additives in gun propellant formulation to reduce the barrel erosion [1367]. Table 77 provides a summary of the physical and thermodynamic properties of these and a few other materials.

## 20.8 —NH—Linked s-Tetrazyl Amines

### 20.8.1 3,6-Bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine (BTATz)

3,6-Bis(1*H*-1,2,3,4-tetrazol-5-ylamino)-1,2,4,5-tetrazine, *N,N'*-bis(1*H*-tetrazol-5-yl)-1,2,4,5-tetrazine-3,6-diamine; 1,2,4,5-tetrazine-3,6-diamine, *N*3,*N*6-bis(2*H*-tetrazol-5-yl)-; 1,2,4,5-tetrazine-3,6-diamine, *N,N'*-bis(1*H*-tetrazol-5-yl)-; *N*3,*N*6-bis(2*H*-tetrazol-5-yl)-1,2,4,5-tetrazine-3,6-diamine, 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine, 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylimino)-1,2,4,5-tetrazine, C<sub>4</sub>H<sub>4</sub>N<sub>14</sub>, CAS RN [254879-86-2], *M* = 248.17 g/mol, with a nitrogen content of 79.017%N, has a density of 1.76 g/cm<sup>3</sup>, melts at 537 K (264 °C), and has an enthalpy of formation of +883 kJ/mol (+211 kcal/mol).

#### 20.8.1.1 Preparation of BTATz

The synthesis and characterization of 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylamino)-1,2,4,5-tetrazine (BTATz) has been reported in [1368–1370]. It is most conveniently prepared by treating BDT with commercially available anhydrous 5-aminotetrazole in hot

sulfolane. The enthalpy of formation is +883 kJ/mol (+211 kcal/mol). BTATz is fairly stable, having a DSC onset of exotherm at 537 K (264 °C), and is friction insensitive. Although pure BTATz is fairly sensitive to spark initiation at 0.36 J of capacitive energy, it is easily desensitized through the addition of a binder such as Kel-F or polyethylacrylate.

3,6-Bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine was synthesized using triaminoguanidinium nitrate and 5-aminotetrazole as the starting materials. This synthesis was a four-step process, including cyclization, oxidation, and dehydrogenation followed by nucleophilic substitution [1371]. The structure of BTATz was identified by IR, <sup>1</sup>H and <sup>13</sup>C NMR, and elemental analysis. Some important properties of BTATz have been determined as follows: density of 1.76 g/cm<sup>3</sup>, melting point of 537–558 K (264–285 °C), detonation velocity of 7520 m/s, burning rate of 5.6 mm/s (at 101 kPa), pressure exponent 0.49, DSC exothermic peak temperature of 593 K (320 °C).

BTATz was synthesized by a condensation reaction of triaminoguanidine nitrate with 2,4-pentanedione. This was followed by oxidation and substitution reactions [1372]. The product was characterized by elemental analysis, IR, NMR, and DSC. Instead of nitrogen dioxide/*N*-methylpyrrolidone, acetic acid/sodium nitrite was an oxidation agent. This reduced the cost and simplified the process. The synthesis, characterization, and quantum chemistry study of 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine provided additional information on this highly energetic compound. Quantum mechanical calculations provided stable geometric configuration and bond orders. It also predicted the vibrational frequencies, IR spectrum, and thermodynamic properties at different temperatures. The pyrolysis of BTATz proceeds via a transition state and the activation energy of the ring-opening reaction of the tetrazole was deduced.

The advantages of BTATz are that it is impact insensitive, non-explosive, non-pyrophoric, and it is an inflammable solid that decomposes rapidly without flame and produces mostly nitrogen as the main combustion product. BTATz is a solid compound that decomposes primarily to nitrogen gas once initiated by heat. The decomposition is rapid, self-sustained, flameless, and occurs readily over a wide range of chamber pressures. The nitrogen gas produced from BTATz can be used to displace oxygen near a flame, thus extinguishing a fire. Because of these qualities, BTATz has been identified as a component for fire suppression gas generants.

### 20.8.1.2 Properties of BTATz

The properties of 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine (BTATz) were compared to other promising high-nitrogen energetic materials [1308, 1343, 1373]. Because of their highly positive HOFs and higher density, these high-nitrogen compounds are unique in their gas generating ability, produce little to no smoke, and have no leftover residue.

BTATz may form dimers, where two molecules are held together by intermolecular forces. Six optimized stable BTATz dimer pairs were found on the potential energy sur-

face; their electronic structures have been obtained by using DFT calculations [1374]. The largest intermolecular interaction energy of the dimer calculated with BSSE and ZPE correction was  $-68.82 \text{ kJ/mol}$ . An NBO analysis was performed to reveal the origin of the intermolecular interaction. Based on the vibrational analysis, the changes of thermodynamic properties from the monomer to dimer in the temperature range of 200 to 800 K were obtained using statistical thermodynamics methods. The strong hydrogen bonds were found to effectively contribute to dimer formation. The dimerization process can occur spontaneously throughout the temperature range of 200 to 400 K.

Other sources for the properties of BTATz reported  $\rho = 1.76 \text{ g/cm}^3$ ; auto-ignition temperature =  $593 \text{ K} = 320^\circ\text{C}$ ; HOF  $\Delta H_f = +711 \text{ kJ/mol} = 170 \text{ kcal/mol} = 685 \text{ kcal/kg}$ ; measured detonation velocity  $D = 7520 \text{ m/s}$  at a packing density of  $1.76 \text{ g/cm}^3$  [1299]. The vapor pressure of BTATz can be expressed by the equation

$$\ln p = 21.1 - 18000/T$$

where  $p$  is the vapor pressure in atm and  $T$  is the temperature in kelvin. The heat of sublimation is  $150 \text{ kJ/mol}$  ( $35.8 \text{ kcal/mol}$ ). The thermal decomposition of BTATz is governed by the kinetic rate equation

$$k = 2.8 \times 10^{10} \exp(-32090/RT) \text{ s}^{-1}.$$

### 20.8.1.3 Thermal Decomposition of BTATz

The thermal decomposition of BTATz was investigated by using TGA, DSC, and *in-situ* thermolysis rapid-scanning FTIR [1375]. The results showed that the thermal decomposition of BTATz is insensitive to pressure. The thermal decomposition kinetic parameters and equation of BTATz, based on the Ozawa, Kissinger, and Coats-Redfern method, was  $E_a = 317.41 \text{ kJ/mol}$  and  $\log A = 28.07 \text{ s}^{-1}$ . The kinetic equation of BTATz decomposition can be expressed as

$$\frac{d\alpha}{dt} = 1.5 \times 10^{28.07} \exp\left(-3.8178 \times \frac{10^4}{T}\right) (1-\alpha) [-\ln(1-\alpha)]^{\frac{1}{3}}.$$

The primary step in the thermal decomposition of BTATz is the opening of the tetrazine and tetrazole ring. The solid residue after heating to  $738 \text{ K}$  ( $465^\circ\text{C}$ ) consisted of  $\text{NH}_4\text{N}_3$ , a polyamine, and melem, which is a triazine condensation product.

The thermal decomposition characteristics of triaminoguanidinium azotetrazolate (TAGZT), 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine (BTATz), and 3,6-diamino-1,2,4,5-tetrazine-1,4-dioxide (LAX-112) were studied using DTA, DSC, high-pressure DSC (PDSC), TGA-DTA, and T-jump/FTIR [1376]. The thermal decomposition kinetic parameters, the  $E_a$ , and  $\log A$  values of TAGZT, BTATz, and LAX-112 were 231.87, 317.41, and  $175.62 \text{ kJ/mol}$ , 25.01, 28.07, and  $16.20 \text{ s}^{-1}$ , respectively. Other TGA and DSC results suggested that BTATz decomposes in the range of  $538\text{--}623 \text{ K}$  ( $265\text{--}350^\circ\text{C}$ ) and the calculated energy of activation of BTATz decomposition was  $212.69 \text{ kJ/mol}$  [1370].

Based on a combination of the power of AIMD methods and DFT, a study of the thermal decomposition mechanisms of the *s*-tetrazine molecule and five of its derivatives suggested that the *s*-tetrazine molecule undergoes a concerted triple dissociation that is similar to its photolysis mechanism [1377]. The tetrazine ring in BTATz-type tetrazine derivatives may be broken by three modes: a concerted triple dissociation, a concerted double dissociation, or a single dissociation, where the concerted triple dissociation mechanism is generally dominant. The stability of the tetrazine ring can be strengthened by substituents like tetrazolyl. If the stability of substituents is better than that of the tetrazine ring, decomposition occurs first through tetrazine ring-breaking. Otherwise, the substituents decay first.

The thermal stability of 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylimino)-1,2,4,5-tetrazine (BTATz) was examined by isothermal and non-isothermal methods [1313]. In the case of BTATz, the decomposition begins with less thermostable tetrazole fragments that capture the tetrazine ring also. The presence of the preliminary reactions of isomerization during tetrazole ring decomposition is the reason for the large observable activation energy of decomposition (240 kJ/mol = 57.5 kcal/mol) in the temperature interval 523–607 K (250–334 °C). In the combustion wave at higher temperatures, the activation energy of BTATz decomposition had a considerably lower value (128 kJ/mol = 30.7 kcal/mol) that was close to a theoretically calculated one. The temperature distribution in the combustion waves of BTATz was measured at low pressures that allowed the surface temperature dependence vs. pressure to be obtained. The burning of these compounds can be explained by a combustion model with a leading reaction in the condensed phase.

#### 20.8.1.4 Strand Burning Rates of BTATz

BTATz burns at impressive rates and with lower than typical pressure effects [1368, 1369], (see Figure 27). At 1 atm, BTATz has a burn rate of 0.56 cm/s that increases to 7.5 cm/s at 191 atm. The pressure exponent over the same range of pressure calculates to 0.49. This has piqued interest in the propellant community. Like DHT, BTATz burns with little or no flame front. In measurements performed at Sandia Laboratory, BTATz was able to sustain a burn front when packed in capillary glass tubes as small as 250 μm in diameter. The compound and its salts can be used in a propellant composition, including an oxidizer, a binder, and 3,6-bis(1*H*-1,2,3,4-tetrazol-5-ylamino)-1,2,4,5-tetrazine, or its ammonium, hydrazinium, or hydroxylammonium salts. BTATz has a high burn rate as shown in Figure 27, wherein the burn rate of BTATz (with 3 vol.-% of Kel-F 800 resin as a binder) is shown and compared with the burn rate of commonly known materials such as 3,6-dihydrazino-*s*-tetrazine (DHT), 3,3'-diamino-4,4'-azoxyfurazan (DAAF), and HMX. Besides a high burn rate, the plot of the burn rate for BTATz has an unexpectedly low slope that is desirable for some propellant applications.

**Figure 27:** Burning rates of BTATz and other high-nitrogen compounds. (Reproduced and modified from [1369].)

The strand burning rates of 3,6-bis(1*H*-1,2,3,4-tetrazol-5-amino)-2-tetrazine (BTATz) were determined in a windowed combustion bomb and compared to those of di-amino-azo-tetrazine (DAAT) *N*-oxides, DAAT, and hydrazinium nitroformate (HNF) [1378]. The effect of the synthesis procedure on the burning rate and burning rate pressure exponent was measured for a wide range of pressures. It appears that the use of DMF in the final synthetic step not only results in higher burning rate materials but also reduced burning rate pressure exponents. After characterizing the pure compound, the effect of BTATz on ADN burning rate was measured by preparing ADN/BTATZ mixtures and pelletizing them. Pellets of BTATz burn smoothly by themselves at pressures between 1 to 70 atm with a burning rate equation of

$$r_b = 5.6p^{0.49}$$

where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in atm [1299]. The tendency of tetrazines to form solvates (residual solvents) affects their strand burning behavior.

#### 20.8.1.5 BTATz Salts

BTATz is an acid that forms salts with a wide variety of bases. Salts with nitrogen-rich bases that have very high nitrogen contents are preferred. The 1,3-propane diamine salt of BTATz was synthesized by the reaction of 3,6-bis (1*H*-1,2,3,4-tetrazol-5-ylamino)-1,2,4,5-tetrazine (BTATz) with 1,3-propane diamine in DMSO [1379]. Single crystals suitable for XRD measurement were obtained by recrystallization. The

crystals belonged to the monoclinic system, space group  $Cc$  with crystal unit cell parameters of  $a = 2.2699(10)$  nm,  $b = 0.5098(2)$  nm,  $c = 1.6449(6)$  nm,  $\beta = 93.045(15)^\circ$ ,  $V = 1.9008(13)$  nm<sup>3</sup>,  $\rho_c = 1.504$  g/cm<sup>3</sup>, and  $Z = 4$ . The DSC showed that the thermal decomposition of the salt included only an exothermic process.

## 20.9 Other Tetrazine Derivatives

3,6-Dihydrazino-1,2,4,5-tetrazine would be a good constituent of gas generator propellants due to its high nitrogen content (79%) and high enthalpy of formation (519 kJ/mol). It can be prepared by reaction of 3,6-diamino-1,2,4,5-tetrazine with hydrazine [1380].

### 20.9.1 Other Single-Ringed Tetrazine Derivatives

When developing tetrazine-based HEDMs, the HOF as a performance parameter can be measured in a calorimeter bomb or predicted using theoretical calculations. The enthalpies of formation of six 1,2,3,4-tetrazine-based compounds were calculated using a DFT method and by using homodesmotic reaction combinations [1381]. The predicted detonation velocity and pressure were calculated. The detonation performances of two of the compounds were superior to those of CL-20. The detonation velocity, detonation pressure, and oxygen balance of 1,2,3,4-tetrazine-based oxo derivatives can be improved by the partial oxidation of the nitrogen atoms in the tetrazine ring. However, further oxidation causes a reduction of the enthalpies and the specific impulses of the *N*-oxide derivatives. The acidic hydrolysis of 1*H*,2*H*-1,2,4,5-tetrazine-3,6-dicarboxylic acid was instrumental in the discovery of hydrazine in 1889.

### 20.9.2 Other Multi-Ringed (Fused, Annulated) Tetrazine Derivatives

3-Amino-6-(3,5-dimethylpyrazol-1-yl)-*s*-tetrazine (ADMPT), 3-hydrazino-6-(3,5-dimethylpyrazol-1-yl)-*s*-tetrazine (HDMPT) and several other *s*-tetrazine-derived high-nitrogen energetic compounds were synthesized and characterized by IR, elemental analysis, and <sup>1</sup>H NMR and <sup>13</sup>C NMR spectra [1283]. The thermal stability was measured with a DSC at different heating rates. Energetic salts of a three-ringed structure containing triazole, *s*-triazine, and tetrazine rings have been patented [1382].

Triazinotriazolotetrazine

Similar derivatives were made from a di(triazolo)triazine three-ringed structure [1383]. These compounds are suitable as sources of nitrogen in gas generants.

### 20.9.3 Tetrazine *N*-Oxides

If 3,6-diamino-*s*-tetrazine is oxidized, *N*-oxides are formed at the 1- and 4-positions, producing 3,6-diamino-1,2,4,5-tetrazine-1,4-dioxide; 1,2,4,5-tetrazine-3,6-diamine, 1,4-dioxide; 1,4-dioxido-1,2,4,5-tetrazine-1,4-dium-3,6-diamine, DATZO\_2, LAX-112, CAS RN [153757-93-8],  $C_2H_4N_6O_2$ ,  $M = 144.092$  g/mol, with a density of  $1.860$  g/cm<sup>3</sup>, a melting point of  $539$  K ( $266$  °C), an oxygen balance of  $-44\%$ , and an enthalpy of formation of  $+164$  kJ/mol ( $+39.2$  kcal/mol =  $272$  cal/g).

3,6-Diamino-*s*-tetrazine-1,4-dioxide (LAX112)

LAX112 was once extensively studied as an insensitive explosive by Los Alamos National Laboratory (LANL) [1303]. More recent publications referenced its density as  $\rho = 1.86$  g/cm<sup>3</sup>, the auto-ignition temperature as  $T_{\text{ign}} = 463$  K ( $190$  °C), the HOF as  $\Delta H_f = +200.8$  kJ/mol ( $+48$  kcal/mol) =  $+330$  kcal/kg, and a detonation velocity of  $D = 8700$  m/s at a packing density of  $1.86$  g/cm<sup>3</sup>.

3,6-Diamino-1,2,4,5-tetrazine (DATZ), the raw material needed for the synthesis of LAX112, was synthesized from 3,6-bis(3,5-dimethyl-pyrazol-1-yl)-1,2,4,5-tetrazine (BT)

with a yield of 95.3% [1384]. DATZ was oxidized with peroxyformic acid to form 3,6-diamino-1,2,4,5-tetrazine-1,4-dioxide (DATZO\_2) with a yield of 60.2%. The effects of reaction conditions on the yield of DATZO\_2 were studied and the optimum reaction conditions were reported as being: DATZ 1.12 g (0.01 mol), formic acid 200 mL and hydrogen peroxide 4 mL, reaction time 1 h, and reaction temperature 298 K (25 °C). The structures of both DATZ and DATZO\_2 were identified and characterized by IR, NMR, DSC, MS, elemental analysis, and melting point determination.

3,6-Diamino-1,2,4,5-tetrazine-1,4-dioxide (DATZO\_2) was synthesized from 3,6-bis(3,5-dimethylpyrazol-1-yl)-1,2-dihydro-1,2,4,5-tetrazine (BDT) using a two-step reaction sequence, with an overall yield of 46.8% at the 30-g scale [1385]. 3,6-Bis(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine (BT), which was an important synthesis intermediate, was obtained by using oxygen as the oxidizer without  $N_xO_y$ . A series of synthesis and recrystallization methods were developed to yield different particle sizes and crystal morphologies, and their sensitivities were tested. The thermal decomposition of DATZO\_2 was investigated, and the kinetic parameters of decomposition and some indications of governing decomposition mechanisms were obtained.

The thermal decomposition characteristics of 3,6-diamino-1,2,4,5-tetrazine-1,4-dioxide (LAX-112) were studied by DTA, DSC, PDSC, TGA-DTG, and T-jump/FTIR along with those of triaminoguanidinium azotetrazolate (TAGZT) and 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine (BTATz) [1376]. The thermal decomposition kinetic parameters, the  $E_a$ , and log A values of TAGZT, BTATz, and LAX-112 were 231.87, 317.41, and 175.62 kJ/mol and 25.01, 28.07, and 16.20 s<sup>-1</sup>, respectively.

An energetic tetrazine-1,3-dioxide, 5,7-dinitrobenzo-1,2,3,4-tetrazine-1,3-dioxide (DNBTDO), was synthesized and characterized as an energetic material in terms of performance ( $V_{det}$  8411 m/s;  $p_{CJ}$   $3.3 \times 10^{10}$  Pa at a packing density of 1.868 g/cm<sup>3</sup>), mechanical sensitivity (impact and friction as a function of grain size), and thermal stability ( $T_{dec}$  = 477 K = 204 °C) [1386]. DNBTDO exhibited a sensitivity slightly higher than that of RDX and a performance slightly lower (96%) than that of RDX.

Another high-energy tetrazine *N*-oxide is 1,4-diamino-2,3,5,6-tetrazine-2,5-dioxide (TZX). Despite a high detonation velocity and a predicted CJ pressure that is comparable to that of RDX, TZX performed relatively poorly in the cylinder test [1387, 1388]. Theoretical and computational analyses showed this to be the result of a low heat of detonation.

5-Amino-(*tert*-butyl-NNO-azoxy)-1,2,3,4-tetrazine-1,3-dioxide reacts with nitronium tetrafluoroborate to form 5-amino-6-nitro-1,2,3,4-tetrazine-1,3-dioxide [1389]. A plausible reaction mechanism involves the electrophilic substitution of the *tert*-butyl-NNO-azoxy group by the nitro group.

3-Amino-6-nitro-1,2,4,5-tetrazine-2,4-dioxide,  $C_2H_2N_5O_4$ ,  $M$  = 160.07 g/mol, has a very low auto-ignition temperature of 383 K (110 °C) and an enthalpy of formation  $\Delta H_f$  of +180 kJ/mol (+43 kcal/mol = +245 kcal/kg).

*N*-oxides of 3,3'-azo-bis(6-amino-1,2,4,5-tetrazine), diaminoazotetrazine poly(*N*-oxide), DAATO, DAATOx, can have 3.5–3.9 oxygen atoms per molecule. Those carrying an uneven number of oxygen atoms are called “DAATO-3.5.” The 3.5 represents the average oxygen atom content on the ring (5 is maximum). 3,3'-Azoxybis(6-amino-5-*N*-oxide-s-tetrazine), DAATO3.5, DAATO-3.5, is a high-nitrogen compound that derives its energy mostly from the high HOF rather than the oxidation of a carbon backbone. The high nitrogen content of the DAAT building block also results in a high density, and the low content of carbon and hydrogen allows for the easy achievement of a good oxygen balance. In one test, DAATOx was found to have the fastest strand burning rate of any known organic material and it sustained combustion even at very small diameters. For the 3.5-oxygen-per-molecule composition, the molecular mass would be 276.16 g/mol, and the enthalpy of formation for that composition would be +628 kJ/mol (+150.0 kcal/mol = +543 cal/g). Other literature sources gave the following properties for DAATO3.5: density  $\rho = 1.88 \text{ g/cm}^3$ , auto-ignition temperature  $T_{\text{ign}} = 450 \text{ K}$  (177 °C), enthalpy of formation  $\Delta H_f = +548 \text{ kJ/mol}$  (+131 kcal/mol = 440 kcal/kg).

The initiation and secondary reactions from the decomposition of DAATO-3.5 were examined by DSC and TGA/MS [1390]. It was found that the stability of the oxidized compound reduces significantly compared to its building block. A rapid decomposition was observed to begin around 538 K (265 °C), with the release  $\text{N}_2$  and NO as the major species. It was believed that isocyanic acid (HNCO) is released in large quantities too, however, its relative concentration has not yet been quantified. Species observed in smaller quantities included HCN,  $\text{N}_2\text{O}$ ,  $\text{H}_2\text{O}$ , and  $\text{CO}_2$ . A significant amount of the residue is believed to be tetrazines, which are known to resist decomposition at the considered temperatures during the relatively short duration of the experiment.

#### 20.9.4 Ditetrazinetetroxide

Based on computations and similarity with other energetic compounds, it was predicted that di-1,2,3,4-tetrazine tetraoxide and its isomer should make good explosives. While, as of 2015, neither had yet been synthesized, it has been suggested that the semi-polar  $\text{N} \rightarrow \text{O}$  linkages on alternate nitrogens will have a stabilizing effect.

Di-1,2,3,4-tetrazine tetraoxide

*iso*-Di-1,2,3,4-tetrazine tetraoxide

The accurate, full-length name for di-1,2,3,4-tetrazine tetraoxide should be [1,2,3,4]tetrazino-[5,6-e]-[1,2,3,4]tetrazine-[1,3,5,7]tetraoxide. It is known as  $C_2N_8O_4$ , DTTO, TTTO,  $M = 200.07$  g/mol. The most stable conformation of TTTO is a planar structure with  $C_{2h}$  symmetry. Using various high-level *ab initio* methods together with DFT-based models, the enthalpies of formation of TTTO at 0 K and standard state were calculated [1391]. The predicted high HOF ( $>200$  kcal/mol), high density ( $>2.0$  g/cm<sup>3</sup>), planar non-polar electronic structure, and the perfect oxygen balance indicate that TTTO should be a HEDM with exceptional performance.

Theoretical quantum mechanical MO calculations were carried out for the isomeric di-1,2,3,4-tetrazine tetraoxides (DTTO and iso-DTTO) [1392]. Detonation pressure and detonation velocity of these compounds are dominated by the densities and not so much by the HOFs. By 2015, DTTO and iso-DTTO were still unknown. The crystal densities were predicted using several different methods resulting in similar densities and explosion parameters. Based on predicted density, DTTO and iso-DTTO could match, or substantially outperform, the best state-of-the-art explosives such as CL-20.

Attempts to prepare a similar molecule containing two carbon atoms that are not part of a phenyl ring, 6-phenyl-[1,2,3]triazolo[4,5-e]-1,2,3,4-tetrazine, PTAT, using a complex 15-step synthesis route had only mixed success [1393]. This compound was chosen as a model compound to test the hypothesis that alternating oxygen substitution on the nitrogen atoms results in a pronounced increase in thermal stability. Only the first ten of 15 steps were successfully completed, with an overall yield of 13%. Predicted properties of DTTO are: density  $\rho = 1.90$  g/cm<sup>3</sup>; HOF (liquid) = 874 kJ/mol = 209 kcal/mol; HOF (solid) = 862 kJ/mol = 206 kcal/mol; detonation velocity  $v_D = 9.71$  km/s; detonation pressure  $p_D = 43.2$  GPa = 432 kbar [1394].

Another model compound made by a four-step synthesis was 6-(tert-butyl-NNO-azoxy)-5-methylthio-1,2,3,4-tetrazine-1,3-dioxide, which was supposed to be a precursor of tetrazino-tetrazine-1,3,6,8-tetraoxide [1395]. Eventually, one group of chemists succeeded in the synthesis and characterization of [1,2,3,4]tetrazino-[5,6-e][1,2,3,4]tetrazine 1,3,6,8-tetraoxide (TTTO) [1396]. It was synthesized in a ten-step synthesis from 2,2-bis(tert-butyl-NNO-azoxy)acetonitrile. The synthetic strategy was based on the sequential closure of two 1,2,3,4-tetrazine 1,3-dioxide rings by the generation of oxodiazonium ions and their intra-molecular coupling with tert-butyl-NNO-azoxy groups. The molecular structure of TTTO was confirmed by single-crystal XRD.

### 20.9.5 Polymeric Tetrazines

In a search for high-nitrogen content polymers suitable as highly energetic binders for solid propellants, linked chains, or networks of triazine and tetrazine rings have been synthesized and tested. The synthesis of polyhetarylenes containing s-tetrazine and other nitrogen heterocycles (pyridine or s-triazine) involved the polymerization of di- or triamidrazones, leading to a linear or hyperbranched dihydrotetrazine-based

assembly [1397]. The poly-(triazinylene-tetrazinylene) material was described as one of the most nitrogen-rich polymers ever made.

## 20.10 Fused Heterocyclic Ring Structures

### 20.10.1 Fused Heterocyclic Ring Structures with Two Rings

Quantum-chemical calculations of hypothetical molecules of octaazanaphthalene and its *N*-oxides were performed by a modified neglect of differential overlap (MNDO) method and with full geometry optimization [1398]. The paths of probable decomposition reactions of these compounds were outlined. Compounds with more pronounced alternation of charges on adjacent atoms (such as in triazine) were shown to be more thermodynamically favorable and thermally stable than molecules with identical charges on adjacent atoms [1399].

An intermediate in the synthesis of *trans*-1,4,5,8-tetranitro-1,4,5,8-tetraazadecalin (TNAD), *trans*-1,4,5,8-tetraazadecalin, was first prepared from glyoxal and ethylenediamine and then nitrated to TNAD with  $\text{HNO}_3$  in acetic acid anhydride [1400, 1401]. The nitration was carried out in three steps.

1,4,5,8-Tetranitro-1,4,5,8-tetraazadecalin

*trans*-1,4,5,8-Tetranitro-1,4,5,8-tetraazadecalin, decahydro-1,4,5,8-tetranitropyrazino-[2,3-*b*]pyrazine; pyrazino[2,3-*b*]pyrazine, 1,4,5,8-tetranitro-2,3,4a,6,7,8a-hexahydro-

pyrazino[2,3-*b*]pyrazine, decahydro-1,4,5,8-tetranitro-, *trans*-; 1,4,5,8-tetranitro-1,4,5,8-tetraazadecahydronaphthalene,  $C_{10}H_{10}N_8O_8$ , TNAD, CAS RN [83673-31-8],  $M = 322.19$  g/mol, melts at 505–507 K (232–234 °C) and has a density of 1.80 g/cm<sup>3</sup> and an enthalpy of formation of +96.2 kJ/mol (+23.0 kcal/mol = +71 cal/g). This is a quadruple nitramine, and its synthesis and properties should also have been included in chapter “Nitramines” of *Encyclopedia of Liquid Fuels*.

Several possible pathways of the thermal decomposition of 1,4,5,8-tetranitro-1,4,5,8-tetraazadecalin were examined using computational chemistry and DFT. The results were compared with experimental data, revealing the most probable pathway for TNAD thermal decomposition [1402].

A systematic study of the thermolysis mechanism and stability of a series of energetic cyclic nitramines (*trans*-1,4,5,8-tetranitro-1,4,5,8-tetraazadecalin isomers) was performed using DFT and semi-empirical MO calculations [1403]. BDE and activation energies ( $E_a$ ) of the thermolysis processes were predicted. The effect of nitroamino groups on the thermal stability and pyrolysis mechanism of the bicyclic nitramines was evaluated by predicting the BDE and  $E_a$ . The results indicated that thermal stabilities and decomposition mechanisms of the bicyclic nitramines derived from the BDE, activation energy, and static electronic parameters were consistent. Homolysis of the N–NO<sub>2</sub> bonds is the initial step in the thermolysis of the bicyclic nitramines. The *meta*-isomers were more stable than the *para*-isomers, and the *ortho*-isomers were the most sensitive.

DFT calculations were performed to relate the structures to the properties of crystalline *trans*-1,4,5,8-tetranitrotetraazadecalin [1404]. The calculated crystal structure compared well with the experimental data. The crystal is an electric insulator. All the atoms of TNAD make up both the lower and the higher energy bands. The projection of the electron density of state demonstrated that the N–NO<sub>2</sub> bond is the most reactive region of the material. The lattice energy was predicted to be –155.13 kJ/mol, which is consistent with previous studies, whereas it was underestimated by the other methods (–70.41 and –74.33 kJ/mol, respectively). The optical properties under ambient conditions were investigated, including dielectric function, absorption coefficient, and reflectivity. The calculated absorption spectra showed several absorption peaks in the fundamental absorption region. These were believed to be associated with different exciton states in the crystal.

The kinetics and mechanism of thermal decomposition of *trans*-1,4,5,8-tetranitro-1,4,5,8-tetraazadecalin (TNAD) have been studied using TGA, IR spectroscopy, and pressure differential scanning calorimetry [1405]. The IR spectra of TNAD have also been recorded, and the kinetics of thermolysis has been followed using non-isothermal TGA. Based on the activation energy of the solid-state process, the reaction mechanism of the exothermic process of TNAD decomposition was classified as a nucleation and nuclear growth reaction and a 2-D diffusion chemical reaction.  $E_a$  and  $\ln A$  of the two processes were 330.14 kJ/mol and 29.93, or 250.30 kJ/mol and 21.62, respectively.

Tetraazadecalin (TAD), a precursor for the synthesis of TNAD, was made by aldehyde amine cyclization from glyoxal and ethylenediamine as the primary material. Tetraazadecalin hydrochloride was obtained via the acidification of TAD [1406]. Nitration of tetraazadecalin hydrochloride with a nitrating acid mixture of nitric acid and acetic anhydride formed 1,4,5,8-tetranitro-1,4,5,8-tetraazadecalin (TNAD). The overall yield of TNAD was >43%. The purity of TNAD was 98%. The structure of TNAD was characterized by IR, NMR, and elemental analysis.

## 20.10.2 Bridged and Caged Heterocyclic Ring Structures

### 20.10.2.1 Diazabicyclohexane

1,5-Diazabicyclo[3.1.0]hexane-type compounds (DABHs) were identified as promising liquid hypergolic fuels [1407]. The synthesis process and purification of DABHs, 1,5-diazabicyclo[3.1.0]hexane (DABH, CAS RN [13090-31-8]), 6-methyl-1,5-diazabicyclo[3.1.0]hexane (MDABH, CAS RN [6794-96-3]), 6-ethyl-1,5-diazabicyclo[3.1.0]hexane (EDABH), and 6,6-dimethyl-1,5-diazabicyclo[3.1.0]hexane (DMDABH, CAS RN [104518-69-6]) were optimized [20]. The densities of DABHs were greater than 1.0 g/cm<sup>3</sup> and the viscosities were about 2.40–2.63 mPa s. The DABHs are less volatile than methylhydrazines and the freezing points varied considerably for different degrees of alkylation.

The enthalpies of formation of DABHs were calculated as 129.2–276.2 kJ/mol, which was higher than those of MMH, unsymmetrical dimethylhydrazine (UDMH), or hydrazine. The ignition delay time of DABH with dinitrogen tetroxide was 1 ms, and the ignition delay times of other alkyl-substituted DABHs was 4–11 ms, which indicated their merits as hypergolic fuels.

1,5-Diazabicyclo[3.1.0]hexane (DABH) was evaluated as a potential hypergolic liquid fuel [1408]. The physical and energetic properties of DABH were compared to those of 2-(dimethylamino)ethyl azide (DMAZ), and MMH. The ignition delay time of DABH with dinitrogen tetroxide was 1 ms, which was shorter than DMAZ and similar to that of MMH. A toxicology experiment showed that LD<sub>50</sub> of DABH was 621 mg/kg, which suggested that DABH was less toxic than the other liquid propellants. Thermal decomposition experiments showed that the apparent activation energy ( $E_a$ ) was about 66.3 kJ/mol and the pre-exponential factor was obtained.

### 20.10.2.2 Tetraazabicyclooctane

A DFT method was used to study the molecular geometry, electronic structure, IR spectrum, and thermodynamic properties of cage-tetranitrotetraazabicyclooctane [1409]. The HOF ( $\Delta H_f$ ) and calculated density were used to calculate the predicted detonation properties using K-J equations. The thermal stability of 3,5,7,10,12,14,15,16-octanitro-3,5,7,10,12,14,15,16-octaaza-heptacyclo [7.5.1.1<sup>2,8</sup>.0<sup>1,11</sup>.0<sup>2,6</sup>.0<sup>4,13</sup>.0<sup>6,11</sup>]hexadecane, also known as cage-tetranitrotetraazabicyclooctane, 1,3,4,6-tetranitro-2,3a,5,6a-tetrahydroimidazo[4,5-d]imidazole,  $C_4H_6N_8O_8$ , “bicyclo HMX,” CAS RN [473796-67-7], was investigated by calculating the BDE. Both the predicted detonation velocity of 9.96 km/s and the detonation pressure of 47.47 GPa are better than those of CL-20.

Tetranitrotetraazabicyclooctane

The calculated results showed that the N—NO<sub>2</sub> bond is a trigger during the thermolysis initiation process. The predicted crystal structure obtained by molecular mechanics methods belongs to space group  $Pna2_1$ , with cell parameters  $a = 12.840 \text{ \AA}$ ,  $b = 9.129 \text{ \AA}$ ,  $c = 14.346 \text{ \AA}$ ,  $Z = 6$ , and  $\rho = 2.292 \text{ g/cm}^3$ . However, this predicted crystal structure does not match the experimental measurements for *cis*-2,4,6,8-tetranitro-1*H*,5*H*-2,4,6,8-tetraaza-bicyclo-[3.3.0]-octane,  $C_4H_6N_8O_8$ , monoclinic,  $P2_1$ ,  $a = 8.5979(2) \text{ \AA}$ ,  $b = 6.9495(2) \text{ \AA}$ ,  $c = 8.9726(2) \text{ \AA}$ ,  $\beta = 101.783(2)^\circ$ ,  $V = 524.83(2) \text{ \AA}^3$ , and  $Z = 2$  [1410].

### 20.10.2.3 Hexamethylenetetramine (Urotropine)

Hexamethylenetetramine, also known as urotropine, hexamine, 1,3,5,7-tetraazatricyclo[3,3,1,<sup>3,7</sup>]decane, tetraazaadamantane, methenamine,  $C_6H_{16}N_4$ , CAS RN [100-97-0],  $M = 144.22 \text{ g/mol}$ , is a bridged heterocyclic amine formed from formaldehyde and ammonia. The structure of hexamethylenetetramine is shown in Figure 28.

It is a crystalline solid and forms monobasic salts with strong acids. Other urotropinium salts are formed as quaternary salts by methylation with methyl iodide. One or two amine groups in hexamethylenetetramine can be quaternized. The iodide ion(s) can then be replaced with more energetic (oxidizing) anions in

**Figure 28:** Molecular structure of hexamethylenetetramine.

**Table 78:** Physical properties of hexamethylenetetramine.

| Property                     | SI units                                     | Other units                                   |
|------------------------------|----------------------------------------------|-----------------------------------------------|

| Enthalpy of formation, 298 K | +120.499 kJ/mol                              | +28.9 kcal/mol                                |
| Entropy of formation, 298 K  | 163.385 kJ mol <sup>-1</sup> K <sup>-1</sup> | 39.05 kcal mol <sup>-1</sup> °C <sup>-1</sup> |

a metathetical reaction with silver salts of the oxidizing acid. The physical properties of hexamethylenetetramine are summarized in Table 78.

### Physical Properties of Urotropinium Salts

Urotropine forms energetic salts when paired with energetic anions. The initial preparation of urotropinium salts was carried out in the 1950s and, subsequently, the syntheses of a variety of urotropinium salts were reported.

Urotropinium nitrate, *N*-methylurotropinium azide, dinitramide, and azotetrazolate salts have been prepared and characterized using analytical and spectroscopic (<sup>1</sup>H, <sup>13</sup>C, <sup>14</sup>N NMR, IR, Raman) methods [1411]. The structures of all four compounds have been determined using XRD. Hexamethylenetetramine dinitrate can be prepared from hexamethylenetetramine and nitric acid of medium concentration. It is an important precursor in the production of RDX using the Bachmann method, although it may not be isolated as such [1412].

Hexamethylenetetrammonium salts (formed from hexamethylenetetramine with energetic anions: 3,5-dinitropyrazolate, 4,5-dinitroimidazolate, 3,5-dinitro-1,2,4-triazolate, 5-nitrotetrazolate, perchlorate, nitrate, and azide) were synthesized

and characterized [1413]. The structure of *N*-methyl-hexamethylenetetrammonium 3,5-dinitro-1,2,4-triazolate, was confirmed by XRD. The standard enthalpies of formation for the new salts were calculated by using the computationally feasible DFT and MP2 methods in conjunction with an empirical approach based on the densities of the salts. The calculated values ranged from  $\Delta H_f^\circ = -30.6$  to  $+468.8$  kJ/mol where the experimental densities were  $>1.35$  g/cm<sup>3</sup>.

Urotropinium nitrate forms colorless crystals, m.p. 430–434 K (dec.) (157–161 °C) and density  $\rho = 1.47$  g/cm<sup>3</sup>. It can be prepared by the reaction of urotropine with nitric acid. *N*-methylurotropinium azide is a white solid, m.p. 438–443 K (dec.) (165–170 °C) and density 1.4 g/cm<sup>3</sup>. *N*-Methylurotropinium azotetrazolate forms yellow crystals, m.p. 181–184 °C (dec.) and density 1.46 g/cm<sup>3</sup>. These salts can be prepared from either the corresponding iodide or sulfate. Because of the high sensitivity and explosive nature of anhydrous silver azide, an alternative route using sodium azide with *N,N*-dimethylurotropinium diiodide was recommended. Tables 79 and 80 provide summaries of the properties of urotropinium salts. Other sources report the enthalpy of formation of urotropinium dinitrate as  $= -1417.7$  kJ/kg  $= -377.4$  kJ/mol  $= -338.8$  cal/g  $= -90.2$  kcal/mol.

### Chemical Properties of Urotropinium Salts

The oxygen balance of urotropinium dinitrate is  $-78.3\%$ . Hexamethylenetetramine forms complexes with metal salts. Those formed with metal perchlorates are of interest as energetic materials. The kinetics and mechanism of thermolysis of hexamine metal perchlorates have been investigated [1414].

**Table 79:** Physical properties of urotropinium salts.

| Compound name                               | Gross formula                                                   | Melting point  |                | Density<br>g/cm <sup>3</sup> | Enthalpy of formation |          | References |

Data source: [482].

### Safety Properties of Urotropinium Salts

The impact sensitivity of urotropinium dinitrate is 15 N m. The friction sensitivity is defined as a reaction at 240 N pistil load. In the lead block test, a 10-g sample will enlarge the cavity by 220 cm<sup>3</sup>. Urotropinium dinitrate is an intermediate in the production of RDX.

#### 20.10.3 Bridged-Ring HMX Precursors

Dinitropentamethylenetetramine, 1,5-endo methylene-3,7-dinitro-1,3,5,7-tetrazacyclooctane, DPT, is a precursor or an intermediate of hexogen (RDX) and octogen (cyclotetramethylene tetramine, HMX) synthesis. Dinitropentamethylenetetramine (DPT) can be made by starting from urea (without the isolation of intermediates) by nitration, hydrolysis, and Mannich condensation, with a total yield of 63.2%. The reaction mechanism of one-pot synthesis of DPT was studied by isolating and capturing intermediates and by isotope tracing experiments [1415]. The stable intermediates dinitrourea, nitramide, and bis(hydroxymethyl)nitroamine were isolated, and the active intermediate 1-nitro-hexahydrotriazine was captured by benzenesulfonyl chloride. The <sup>2</sup>H (deuterium, which is also abbreviated as D) labeled DPT (DPT-D) was synthesized by the reaction of CD<sub>2</sub>O with NH<sub>3</sub> and bis(hydroxymethyl)nitroamine. The analysis results from <sup>1</sup>H NMR and MS of DPT-D indicated that, in the course of

the reaction, bis(hydroxymethyl)nitroamine decomposed into  $\text{CH}_2\text{O}$  and nitramide, and the small molecule species arranged themselves randomly to form triazine then DPT. DPT can be synthesized by a one-pot method starting with urea [1416]. Without isolation from intermediates, DPT was obtained by nitration, hydrolysis, and Mannich condensation. The yield of DPT was up to 65.2%.

Another process for the preparation of DPT used sulfuric acid, hexamine dinitrate, and formalin [1417]. The yield of crude product could be improved from 30% (literature value) to 60%. The purity of the product was better than 98% [1418].

The crystal structure of dinitropentamethylenetetramine, DPT, is monoclinic, space group  $P2_1/c$  with unit cell parameters of  $a = 9.345 \text{ \AA}$ ,  $b = 8.284 \text{ \AA}$ ,  $c = 11.566 \text{ \AA}$ ,  $\beta = 105.6^\circ$ ,  $Z = 4$ , and  $\rho = 1.682 \text{ g/cm}^3$  [1419]. The two  $\text{N}-\text{NO}_2$  groups in the DPT molecule are planar, with two nitramine carbons raised out of the plane.

## 21 Azacubanes, Azaquadricyclanes, and Azaadamantanes

Cubanoid structures called azacubanes, in which one or more CH groups in the corner of the cube have been replaced by nitrogen, have been synthesized and tested as energetic materials. Of special interest are those azacubanes that carry explosophoric groups, such as nitro groups or azido groups.

Cubane was first synthesized in 1964. However, as of 1990, its unsubstituted heterocyclic analog, 1,3,5,7-tetraazacubane, had not yet been synthesized. The presence of four nitrogen atoms in the cubane skeleton distorts the geometry of the cube, causing highly strained bond angles. This may be due to a combination of several factors such as non-bonding interactions and other repulsive effects of the nitrogen lone electron pairs.

Energetics and charge distributions in azacubanes ( $\text{C}_{8-x}\text{N}_x\text{H}_{8-x}$ ) have been calculated using *ab initio* and hybrid density functional methods and the topography of the molecular electrostatic potential and the electron density of azacubane conformers have been investigated [1420]. From diazacubane to hexaazacubane, the lowest-energy conformers have nitrogen atoms occupying the opposite face opposite corners of a cube. Electrostatic potential studies have shown that the successive insertion of nitrogen in place of CH groups of cubane engenders smaller and more localized electron-rich regions around the nitrogens of a cube. The bond ellipticity and the electron density at the bond critical point of the  $\text{X}-\text{N}$  bonds ( $\text{X} = \text{C}$  or  $\text{N}$ ) in a cubanoid increase from azacubane to octaazacubane. The HOFs of azacubanes calculated by an isodesmic reaction approach using different levels of theory correlated well with the electron density at the bond critical point of  $\text{X}-\text{N}$  ( $\text{X} = \text{C}$  or  $\text{N}$ ) bonds in a cubanoid.

The enthalpies of formation of several polynitrohexaazaadamantanes (PNHAA's) have been calculated by designing isodesmic reactions [1421]. The enthalpies of formation were found to correlate with the number ( $n$ ) and the spatial orientations of nitro groups. Detonation velocities ( $D$ ) and detonation pressures ( $P$ ) were estimated

for PNHAAs by using the K-J equations. It was found that  $D$  and  $P$  increase as  $n$  ranges from one to six, and PNHAAs with four to six nitro groups are very energetic. When  $n$  is over six, the density  $\rho$  of PNHAAs slightly increases; however, the chemical energy of detonation ( $Q$ ) decreases so greatly that both  $D$  and  $P$  decrease. The calculations on BDE suggest that the N—N bond would be the trigger bond during the pyrolysis initiation process of each PNHAA. As  $n$  increased, N—N BDE ( $E_{\text{N-N}}$ ) decreased on the whole, which means that the relative stability of PNHAAs decreases. All  $E_{\text{N-N}}$ (s) of PNHAAs were more than 125 kJ/mol (30 kcal/mol). Considering the synthesis difficulty and the performance as an energetic compound, 2,4,6,8,10-pentanitrohexaazaadamantane was recommended as the most promising candidate.

In the caged cubane molecule  $(\text{CH})_8$ , the replacement of CH groups by N atoms increases the content of nitrogen while reducing the content of hydrogen. A series of caged molecules  $(\text{CH})_x\text{N}_{8-x}$  ( $0 \leq x \leq 8$ ) were studied for: **(1)** molecular geometries and electronic structures, **(2)** the analysis of the electronic structure using NBO and atoms in molecules methods, and **(3)** some physico-chemical properties such as the dipole moments. IR vibrational spectra, NMR chemical shifts, HOFs, and relative specific impulses were calculated [1422]. The studies showed that these molecules should be useful energetic materials.

The gas phase enthalpies of the formation of highly nitrated azacubanes have been calculated via isodesmic reactions in which the azacubane cage skeleton is not destroyed [1423]. After the full nitration of 1,4-diazacubane or 1,3,5,7-tetraazacubane, the weakest C—N bond on the 1,3,5,7-tetraazacubane cage skeleton strengthens slightly. However, it weakens on the 1,4-diazacubane cage skeleton. For highly nitrated azacubanes, the introduction of  $-\text{NH}_2$  group results in the destabilization of the neighboring C—N bond on the cage skeleton. The shock stability of 2,4,6,8-tetranitro-1,3,5,7-tetraazacubane (TNTAzC) is superior to that of 2,3,5,6,7,8-hexanitro-1,4-diazacubane (HNDaZC). The detonation velocity and pressure for TNTAzC were predicted to reach 11 km/s and 101 GPa, respectively.

Studies have suggested that ONC is one of the most powerful HEDMs currently known. On the other hand, 2,4,6,8-tetranitro-1,3,5,7-tetraazacubane (TNTAC) may also be a promising HEDM due to its high nitrogen content and high crystal density. DFT and molecular mechanics methods were used to study the crystal structure, IR spectrum, electronic structure, thermodynamic properties, gas-phase and condensed-phase HOF, detonation performance, and the pyrolysis mechanism of TNTAC [100]. TNTAC has a predicted density of about 2.12 g/cm<sup>3</sup>, and its detonation velocity (10.42 km/s) and detonation pressure (52.82 GPa) are higher than those of ONC. The space group is  $P2_12_12_1$ , and the corresponding cell parameters are  $Z = 4$ ,  $a = 8.87 \text{ \AA}$ ,  $b = 8.87 \text{ \AA}$ , and  $c = 11.47 \text{ \AA}$ . Both the density of states of the predicted crystal and the BDE of the molecule in the gas phase showed that the cage C—N bond is the trigger bond during thermolysis. The activation energy of the pyrolysis initiation reaction obtained from calculations is 125.98 kJ/mol, which indicated that TNTAC should have good thermal stability.

## 22 Seven-Membered Ring Heterocyclic Compounds

Structure optimization and frequency calculation of six nitro derivatives of 1,3,5-triazepine (triazepane) were performed using a quantum chemical method [1424]. To obtain reliable energy data, single-point energy and the subsequent thermodynamic properties of the species considered were calculated at a fairly high level of theory. Solid-phase HOFs and the crystal density were determined using an electrostatic potential method, utilizing wave function analysis-surface analysis suite code. The result showed that all nitro derivatives possessed highly positive HOFs that increased with an increase in the number of nitro groups attached to the ring skeleton. The crystal densities were in the range of 1.67–1.90 g/cm<sup>3</sup>. Detonation properties of the compounds were estimated using the K-J equations. The results showed that detonation velocity and detonation pressure increased with an increase in the number of nitro groups attached to the ring structure. It was found that all six nitro derivatives of triazepine had better or comparable performance characteristics than the most widely used commercial explosives, such as TNT, RDX, or HMX. 1,3,5-trinitro-1,3,5-triazepine, 1,3,5-trinitro-1,3,5-triazepane, 1,3,5-trinitro-1,3,5-triazacycloheptane, C<sub>4</sub>H<sub>8</sub>N<sub>6</sub>O<sub>6</sub>, CAS RN [5790-78-3], *M* = 236.143 g/mol, yielded a predicted detonation pressure and a detonation velocity of 45.5 GPa and 9.23 km/s, respectively, at a loading density of 1.90 g/cm<sup>3</sup>, which are superior to HMX (*P* = 39.00 GPa and *D* = 9.11 km/s).

1,3,5-Trinitro-1,3,5-triazepine

Azacycloheptane forms a nitrate salt that melts at 393–396 K (120–123 °C). In the DTA, the maximum exotherm peak is 565 K (292 °C) [1202].

## 23 Eight-Membered Ring Heterocyclic Compounds

Heterocyclic compounds containing eight-membered rings with one or more heteroatoms in the ring are relatively rare compared to six-membered ring heterocyclic compounds. The main representative in this group is HMX, which is thermally more stable and a more powerful explosive than RDX.

As the structure of the book at hand evolved over two decades, the RDX and HMX sections were once contained in the chapter on energetic materials for solid propel-

lants, however, the properties of the pure compounds were eventually moved to chapter “Nitramines” in *Encyclopedia of Liquid Fuels*. Applications of solid energetic compounds will be discussed in future volumes on solid propellants.

# Hydrocarbons

## Introduction

The *Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. The topic of hydrocarbon fuels had to be subdivided into several smaller chapters that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are: “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.” The current chapter, “Hydrocarbons,” is a short introduction to the chemistry and applications of hydrocarbons, and is recommended reading before studying any of the more specialized chapters on hydrocarbons.

## 1 Hydrocarbons

Hydrocarbons are the main mode of energy storage for all modes of transportation, be it by land, sea, air, or space. The combustion of hydrocarbons in air or oxygen releases energy that can propel a vehicle, discharging nitrogen, carbon dioxide, and water or only carbon dioxide/carbon monoxide and water. Hydrocarbons retrieved from fossil fuel deposits in liquid or gaseous form are processed in oil refineries to obtain hydrocarbons in a purified state that are suitable to be burned in internal combustion engines, either reciprocating engines in automobiles or rotary turbines in air-breathing jet engines. We will not discuss the use of hydrocarbons as heating fuels or for generation of steam in stationary or mobile steam power plants here because there is not much chemistry involved in such applications and steam-powered rockets are a thing of the past.

Evaluation criteria for hydrocarbon fuels for air-breathing jet engines are quite different from those for rockets. Not every good jet engine fuel must also be a good rocket fuel. For air-breathing engines, the heat of combustion and the density are the main evaluation criteria. For rocket fuels, low-molecular-mass exhaust products are the most desirable property because this allows high exhaust velocities and specific impulses. Density is important only for the pressure-fed systems usually found in missiles and satellites. Pump-fed rocket propulsion systems can handle liquids with a wide range of densities. If density was important for all rocket fuels, liquid hydrogen, with its very low density, would never have made it onto the list of best rocket fuels.

## 1.1 Summary Publications on Hydrocarbon Fuels

The majority of summary publications on hydrocarbon fuels deal with fuels for air-breathing engines, and only very few deal specifically with hydrocarbon fuels for rockets. Since many of these fuels can be used for either application, we deal with them together here, in spite of the fact that this is a book on rocket fuels, not jet engine fuels. The main emphasis will be on the kerosenes RP-1 and RP-2, but we will also consider the growing interest in liquid methane as a rocket fuel. There are combined-cycle engines and air-breathing rocket engines in development which use fuels that were traditionally used only for jet engines (turbojet or ramjet engines). A complete summary of information on a wide range of hydrocarbon fuels is needed for all these applications.

The historic *CPIA/M6 Air-Breathing Propulsion Manual*, which is still available as a loose-leaf ring binder, describes air-breathing engine fuels (missile/ramjet, turbine/jet, and endothermic) and air-breathing engines (ramjets and small or expendable turbojets). It includes data on the chemical and physical properties of many different fuels. The same data are also available online, but to qualified subscribers only, and in a different format – as Liquid Propellant and Fuels Database (LPFD) Datacards. The complete *CPIA/M6 Air-Breathing Propulsion Manual* is available only to JANNAF ERG service subscribers [1]. As of 2020, it was available for \$300 (contains test facilities of air-breathing engines and is available in paper form only). A table of contents of Volume I is shown in Table 1. Several of the units are available for unlimited distribution (Distribution Statement A), which is why they are referenced here. Both CPIA/M6 Volume I and LPFD Datacards are out-of-date and need to be updated. Some distribu-

tion limitations should be relaxed because most of the information contained therein is now also publicly available from other unlimited sources.

Some hydrocarbon fuels have been custom synthesized to meet specific requirements in terms of density and heat of combustion. High-energy-density liquid fuels are critical for volume-limited airbreathing vehicles as they can extend the flight range and increase the payload and can be used as an energetic additive for conventional fuels. Current multi-cyclic high-energy-density fuels were first introduced due to a focus on more efficient and environmentally compatible synthesis routes. A review paper summarized the synthesis, properties, and challenges (especially those that have become apparent in the past decade) of high-energy-density fuels [2].

The book by Zou, Zhang, and Pan on high-energy-density fuels for advanced propulsion contains chapters on the history and basics of aerospace fuels, high-density polycycloalkane fuels, high-density diamondoid fuels, high-energy strained fuels, nanofluid fuels, and hypergolic ionic liquid fuels [3].

More useful than books written on paper or ring-bound manuals would be an electronic database that provides search capabilities and instant access to reliable and verified property data for hydrocarbon fuels. Several publications have dealt specifically with hydrocarbon fuels for cruise missiles [4] or ramjets. See also [5–7].

## 2 Properties of Hydrocarbon Fuels

The volume occupied by missile propulsion systems on-board ships is a major consideration for sea-launched weapon systems, as the space available to house weapons under deck or above deck is minimal. By comparison, weight is of more significance in air-launched systems. A fuel of increased density for a given gravimetric heat of combustion will have an advantage in volume-limited systems. High-energy-density hydrocarbon fuels can be obtained either by synthesizing polycyclic and diamondoid hydrocarbons with cyclic or spherical structures to achieve high density or by synthesizing strained cyclic hydrocarbons, which have not only high density but also higher energy due to the additional strained energy in the molecules. In general, for hydrocarbon fuels, as the density is increased, the gravimetric heat of combustion decreases [8]. To utilize the density increase to its full advantage, the gravimetric heat of combustion should remain at least constant. However, thanks to the ingenuity of some chemists, the new generation of fuels possess increased gravimetric heat of combustion simultaneously with increased density. This is partly due to the strain energy in the molecules. The increased density ( $\rho = 1.2\text{--}1.3\text{ g/cm}^3$ ), and moderate strain energy of pentacyclic or tetracyclic hydrocarbons can contribute to an increased energy output during combustion. By breaking the molecular symmetries of some of these high-freezing fuels by attaching one or several methyl groups to the ring structure, the freezing and boiling points can be decreased significantly.

These three- or four-membered ring and caged ring fuels have distorted C—C bonds, and the strain energies of these strained rings are much higher than those of cyclopentane and cyclohexane rings. This chapter does not contain a separate section on hydrocarbons with strained rings. Instead, sections on hydrocarbons with strained rings are scattered throughout this volume, especially in the “Alkanes,” “Cycloaliphatic Hydrocarbons,” “Kerosenes,” “Jet Fuels,” and “Ramjet Fuels” chapters. Other books contain dedicated chapters that deal more specifically with hydrocarbons with high densities and high energy contents due to strained rings [9].

Hydrocarbon fuels still represent the largest mass fraction of all currently used liquid rocket fuels for boosters in space launch vehicles, although hydrogen (in spite of its low density) is slowly catching up. For rocket propellants, it is desirable to use hydrocarbon fuels that contain as much hydrogen as possible, which is why most hydrocarbon rocket fuels are saturated alkanes. Selection criteria for air-breathing engines and rocket engines differ in that air-breathing engines benefit more from the heat of combustion and high density than from low-molecular-mass exhaust gases. Nevertheless, many fuels that were originally intended for air-breathing jet engines have also been tested as rocket fuels, often only because they were readily available at the petroleum product tank farm next door.

Hydrocarbons are divided into groups according to their chemical structures. Aliphatic hydrocarbons include the alkanes, alkenes, and alkynes (acetylene and homologues), in order of increasing degree of unsaturation. Cycloaliphatic hydrocarbons are a group by themselves and are also of specific interest as fuels for air-breathing propulsion as well as rocket engines. Hydrocarbons containing benzene rings are called aromatic hydrocarbons. They have better thermal stability than most aliphatic hydrocarbons with similar molecular masses, but are rarely used as liquid rocket propellants. If we arranged this chapter on hydrocarbon fuels based on the number of carbon atoms in the molecule, then methane and the lower hydrocarbons would be discussed first, before dealing with hydrocarbons containing more than one carbon atom, such as kerosene.

Alkanes have the best hydrogen:carbon ratio, which is a desirable property for rocket propellants. The best hydrogen:carbon atom ratio is obtained with methane. The hydrogen:carbon atom ratio in methane is 4:1, which cannot be beaten. In spite of this advantage, methane has not been used as a rocket propellant until recently. Aromatic fuels have the lowest hydrogen:carbon ratios and are less suitable for use as rocket fuels.

Alkenes contain carbon-to-carbon double bonds that are characteristic of unsaturated compounds. An antiquated designation for alkenes is *olefins*. Alkenes with one or more double bonds are more susceptible to autoxidation and resin formation during storage, an undesirable property for jet engine fuels and rocket fuels alike. They are more reactive than either alkanes or aromatics, and their presence reduces the storability of liquid fuels because they may polymerize and autoxidize. Alkynes are

derivatives of acetylene and have unique fuel properties. Alkenes and alkynes will be discussed in the chapter “Alkenes and Alkynes.”

## 2.1 Physical Properties of Hydrocarbon Fuels

### 2.1.1 Vapor Pressures of Hydrocarbon Fuels

Vapor pressures of hydrocarbons can be calculated using a group additivity relationship [10]. For instance, plotting the vapor pressures of linear alkanes or cycloalkanes as a function of the number of carbon atoms gives a nearly linear relationship. Group values were derived from experimental vapor pressure data for 326 compounds. The vapor pressures thus predicted ranged from  $10^{-4}$  to 1000 kPa, and the temperature dependence of the group values was given for temperatures from 298 to 500 K.

### 2.1.2 Thermodynamic Properties of Hydrocarbon Fuels

The most important thermodynamic property of hydrocarbon fuels for airbreathing and for rocket propulsion applications is the enthalpy of formation, directly related to the heat of combustion. For the chemist, the architect of ever more energetic molecules, the design of hydrocarbons is a challenging task. Indeed, one can show some examples of the successful synthesis of fuels for which the molecular structures did not even exist on paper several decades ago. A key property that is common to many of these newer synthetic fuels is the strain energy inherent in alicyclic molecules with strained rings [8, 11].

The vibrational frequencies of selected alkylcyclohexanes and related polycyclic molecules consisting of chair- and boat-shaped six-membered rings were calculated using conventional Hartree-Fock theory with a hybrid density functional procedure [12]. The sums of zero-point energies (ZPE) and heat-content ( $H_T - H_0$ ) energies thus obtained were reproduced by an empirical formula featuring only the total number of carbon atoms, the number of tertiary carbons, the number of carbons in the cycle(s), and the number of rings, while the presence of boat rings or the occurrence of gauche-butane interactions play no role in the description of  $ZPE + H_T - H_0$ . Enthalpies of formation calculated on this basis agreed to within 1 kJ/mol (0.24 kcal/mol) with the experimentally determined numbers. Examples calculated included methylcyclohexane, ethylcyclohexane, propylcyclohexane, bicyclo[2.2.2]octane, adamantane, and decalin.

### 2.1.3 Enthalpies of Fusion of Hydrocarbon Fuels

A group additivity method was used for estimating enthalpies of fusion and entropies of fusion for a wide range of hydrocarbons [13]. The group additivity factors were based on experimental fusion enthalpy data for 191 hydrocarbons. The average deviation between experimental and predicted fusion enthalpies was  $\pm 2.34$  kJ/mol

( $\pm 0.56$  kcal/mol). This method was later expanded to include mono- and multi-substituted derivatives as well [14].

## 2.2 Chemical Properties of Hydrocarbon Fuels

### 2.2.1 Thermal Stabilities of Hydrocarbon Fuels

#### 2.2.1.1 Thermal Stabilities of Hydrocarbon Fuels for Combined Cycle Engines

Plans for launch vehicles with air-breathing first stages and rocket upper stages, mixed-mode propulsion, and dual-mode propulsion may benefit from a commonality of fuels on-board the vehicles [15]. Propellant combinations were evaluated for a variety of candidate engines for use in mixed-mode, single-stage-to-orbit applications. The ISTAR Rocket Based Combined Cycle (RBCC) propulsion system would use the same fuel for both modes of propulsion.

In RBCC engines, in addition to its obvious use as a fuel for propulsive purposes, liquid fuel is used to cool system structures regeneratively to temperatures commensurate with presently available structural materials used for leading edges and combustion chamber walls. Insufficient fuel thermal stability limits the use of some hydrocarbon fuels. In a study of the use of high-energy, high-density hydrocarbons in rocket and combined-cycle propulsion systems, the thermal stabilities of RP-1, JP-10, and quadricyclane were assessed using a system for thermal stability diagnostic studies [16, 17]. Whereas JP-10 and RP-1 exhibited reasonable thermal stability, the highly strained quadricyclane molecules rapidly degraded under high-pressure, condensed-phase thermal stress.

#### 2.2.1.2 Coke Deposition Due to Thermal Decomposition of Hydrocarbon Fuels

There are several other sections in this encyclopedia on coke deposition specifically those on coke deposition in kerosene, RP-1, and RP-3 (in the “Kerosenes” chapter). Coke deposition during pyrolysis of hydrocarbon fuel in a mini-channel reduced the effective diameter and increased the pressure drop. It also drastically reduced heat transfer between the flowing liquid and the tubing. A hydraulic resistance method was introduced to quantitatively evaluate coke deposition [18]. Pyrolysis of a hydrocarbon fuel was carried out during 30-min runs in an electrically heated mini-channel (heated length, 508 mm; inner diameter, 2 mm) at fuel temperatures up to 998 K (725 °C) and a supercritical pressure of 4 MPa. The post-test coke evaluation was non-destructive and performed by flowing at normal temperature and pressure. Through comparison with optical microscope visualization, the hydraulic resistance method was shown to be accurate. Experimental results showed that the thickness of coke deposit along the channel, which varied from several to about 130  $\mu\text{m}$ , was a function of film temperature (average of the wall and bulk fuel temperatures). The hydraulic resistance continuously increased, contributing to the coke deposition during fuel pyrolysis. However, the thermal effects of coke layer thickness will reduce the heat transfer.

### 2.2.1.3 Endothermic Fuels

The speed of a hypersonic air-breathing vehicle is limited by aerodynamic heating. While their lack of thermal stability is a detriment to the use of hydrocarbon fuels in rocket engines, for certain applications of hydrocarbon fuels in hypersonic air-breathing jet engines, the ability to use fuels that decompose endothermically as coolants for leading edges and other hot parts of the missile can be an advantage. Some hydrocarbon fuels have been developed specifically to be used as endothermic fuels [19–21]. Dehydrocyclization of normal alkanes to form saturated ring compounds is not highly endothermic and proceeds slowly on known catalysts, and in a subsequent reaction the saturated rings could be further dehydrogenated to form aromatics. Dehydrogenation of normal alkanes and ring fracture of aromatics and cycloalkenes generally require very high temperatures. Catalytic cracking of normal alkanes follows many different reaction routes and produces hydrogen and a medley of saturated and unsaturated hydrocarbon products.

The endothermic dehydrogenation of methylcyclohexane over a Pt/Al<sub>2</sub>O<sub>3</sub> catalyst can approximately double the 2324 kJ/kg (1000 BTU/lb) cooling capability available from the sensible enthalpy of the fuel alone. This should provide cooling sufficient to allow flight speeds into the range of Mach 10 at optimum altitude. However, the application of cooling to the various portions of the aircraft may present formidable problems. Factors that are important in this consideration are thermal stability, reaction rate, reactor weight and volume, heat transfer, pressure drop, combustion characteristics, and the close mating of the cooling system to the aircraft [22].

Endothermic fuels were specifically developed for air-breathing hypersonic propulsion; however, many of the properties of the fuels developed and characterized under the endothermic fuels programs also apply to the design of regenerative cooling jackets in rocket engines. Although this is a book on rocket propellants, the scope of this chapter on hydrocarbon fuels has been expanded to include fuels that were primarily intended for air-breathing propulsion but may be used as rocket propellants as well.

The development of endothermic fuels has stimulated a wide range of hydrocarbon fuel syntheses and characterization. Early development work on endothermic fuels was conducted at Shell Development Company in Emeryville, CA [23]. Consideration of the effect of design parameters on the conditions under which endothermic reactions can be carried out led to the conclusion that space velocities of 50 or higher would be necessary due to volume limitations in high-speed aircraft. The investigation of the feasibility of using hydrocarbons as heat sink fuels for hypersonic aircraft studied both thermal and catalytic endothermic reaction at temperatures up to 1033 K (1400 °F), pressures up to 6.8 MPa (1000 psi), and liquid hourly space velocities up to 260 and 150, respectively. Kinetic rate considerations favor catalytic reactions. Preliminary studies of the dehydrogenation of propane to propene and of methylcyclohexane to toluene were made. Fuels were tested at temperatures up to at least 811 K (1000 °F). Thermal stability was found to decrease in the following order: *n*-dodecane, toluene,

methylcyclohexane. A 94 L/h (25 gallon/h) fuel system simulation test rig was used for determining heat transfer coefficients, heat sinks, and decomposition product compositions.

The dehydrogenation of methylcyclohexane to form toluene and hydrogen over a platinum-on-alumina catalyst is an effective heat sink [24]. Propane dehydrogenation may absorb about 3489 kJ/kg (1500 BTU/lb), but the reaction is neither as clean nor as rapid. The thermal stabilities of molecular types generally increase in the following order: monocyclic aromatic, monocyclic naphthene, bicyclic naphthene, *n*-paraffin. Exclusion of oxygen increases the critical thermal stability temperature by about 111 K (200 °F). The introduction of alkyl groups into either the cyclohexane or benzene rings increases thermal stability.

Both thermal and catalytic endothermic reactions of mono- and bicyclic naphthenes have been considered as heat sinks at temperatures up to 1033 K (1400 °F), pressures up to 6.8 MPa (1000 psi), and liquid hourly space velocities up to 260 and 150, respectively [25]. Using dehydrogenation to the corresponding aromatics over a platinum-on-alumina catalyst, reaction heat sinks of about 2324 kJ/kg (1000 BTU/lb) of feed should be achievable with the lower members of the series, such as cyclohexane, methylcyclohexane, dicyclohexyl, and decalin. Rates of reaction generally increased with alkyl substitution. Activation energies showed variable behavior. Selectivities for the corresponding aromatics were high.

A study of the supersonic combustion characteristics of the decomposition products of endothermic hydrocarbon fuels (propane and methylcyclohexane dehydrogenation fuel systems) was done in order to define the parameters that affect the combustion process and to establish the feasibility of burning these fuels in supersonic combustors [26].

Laboratory studies on the dehydrogenation over Pt/Al<sub>2</sub>O<sub>3</sub> of a number of mixtures of naphthenes included methyldecalin and dicyclohexyl as well as the pure components, along with additional studies on decalin [23]. About 220 dehydrogenation catalysts were prepared using a variety of metals and supports. The thermal stabilities of methylcyclohexane, decalin, and a naphthenic jet fuel were all critically, but uniquely, dependent on the dissolved O<sub>2</sub> concentration in the region below about 10 ppm.

The dehydrogenation of decalin over a platinum/Al<sub>2</sub>O<sub>3</sub> catalyst was studied on a laboratory scale in the temperature region up to 922 K (1200 °F) and at pressures to 10 atm in order to provide kinetic data for the construction of a mathematical model [24]. Testing has shown that catalysts which demonstrate improved activity with methylcyclohexane do the same with decalin, and it has confirmed the observation that improved catalyst stability is associated with a small pore size. Heat transfer studies in a simulated single-tube fuel system have confirmed the mathematical model for the catalytic dehydrogenation of methylcyclohexane up to a heat flux of 1891 kW/m<sup>2</sup> (600000 BTU h<sup>-1</sup> ft<sup>-2</sup>).

Calculations of the cooling requirement for a Mach 8 supersonic combustion ramjet engine under standard conditions indicated that this application would require about 4416 kJ/kg (1900 BTU per pound of fuel) [27, 28]. The possibility of utilizing the dehydrogenation of bridged-ring naphthenes to provide an additional heat sink has been studied, but no suitable catalysts have been found for this reaction. Studies on methods of accelerating the thermal cracking of paraffins by means of additives have shown some promise. In the dehydrogenation of naphthenes over supported platinum catalysts, the stability of the catalyst was found to be inversely proportional to the pore size of the support, and was also affected by the composition of the support. Efforts to induce the dehydrogenation of methylcyclohexane using dispersed catalysts have met with some success.

The endothermic decomposition of normal straight-chain alkanes (e.g., heptane) or methanol may offer more of a heat sink capability than methylcyclohexane or decalin, the two most commonly tested endothermic fuels.

Storable liquid hydrocarbon fuels such as JP-7, JP-8+100, and JP-10 that can undergo endothermic reactions may provide sufficient heat sink capability to enable hypersonic flight without having to resort to cryogenic fuels. A program to develop and demonstrate the endothermic potential of these fuels for hypersonic scramjet cooling used a high-pressure bench-scale reactor to determine the overall heat sinks (including endotherm), endothermic reforming products, and coking rates for the fuels [29]. A baseline fuel, *n*-octane, was also investigated for comparison. The tests were conducted in tubes that simulated a single passage in a practical catalytic heat exchanger/reactor under representative flow conditions. Performance evaluations were primarily based on endotherm measurements and coke deposition. Adequate heat sink capacities were demonstrated for JP-7 and JP-8+100 at elevated pressures using a simple, inexpensive zeolite cracking catalyst. Although JP-10 provided an attractive heat sink, its high carbon-to-hydrogen ratio led to significant coking/fouling problems and potential poisoning of the catalyst, even at relatively low temperatures.

The coking characteristics of the Chinese endothermic hydrocarbon fuel S-1 on Ni-Cr alloy was studied in a laboratory-scale continuous flow reactor system [30]. The carburization of the Ni-Cr alloy surface was examined by EDAX analysis. The coke composition was determined by elemental analysis, which showed that the ratio of hydrogen to carbon in the coke decreased with reaction time. The surface morphology of the coke was determined by SEM after heat treatment at 973–1473 K (700–1200 °C) with a heating rate of 20 K/min applied by a DSC. The results showed that temperature has an important effect on the structure of the coke. The analytical results for soluble coke deposits showed that the intermediate coking products consisted of aromatic compounds and paraffins.

The activities of catalysts for decomposition of endothermic fuels can be improved by depositing the active metal preferentially on the surfaces of catalyst granules or reactor wall coatings [31].

Catalytic cracking of China No. 3 aviation kerosene using a zeolite catalyst was investigated under supercritical conditions [32]. A three-stage heating/cracking system was designed to be capable of heating 0.8 kg kerosene to a temperature of 1050 K and a pressure of 7.0 MPa with a maximum flow rate of 80 g/s. The mass flow rate was found to correlate well with the extent of fuel conversion. The gaseous products obtained from fuel cracking under different conditions were analyzed using GC. Results showed that the average molecular weight of the resulting gaseous products and the fuel mass conversion percentage were strong functions of the fuel temperature and fuel pressure. The fuel conversion was shown to depend on the fuel residence time in the reactor, as expected. The heat sink levels due to sensible heating and endothermic cracking were determined and compared under varying operating conditions. It was found that at a fuel temperature of ~1050 K, the total heat sink reached ~3.4 MJ/kg, with the chemical heat sink accounting for 1.5 MJ/kg.

Nucleate boiling heat transfer may induce oscillation under near-boiling conditions in any fluid, including hydrocarbons and endothermic fuels. The thermo-acoustic instability and heat transfer coefficients of an endothermic hydrocarbon fuel were investigated in a horizontal mini-tube at supercritical pressure [33]. The test section was a CRES 316tube with a length of 240 mm and an inner diameter of 1.6 mm. Experiments were conducted at pressures of 2.5–4.0 MPa, mass fluxes of 800–1200 kg m<sup>-2</sup> s<sup>-1</sup>, and heat fluxes of 665–950 kW/m<sup>2</sup>. A correlation between the heat transfer coefficient and the oscillation intensity indicated that the periodic decrease in wall temperature was accompanied by synchronous increases in the outlet bulk temperature and the pressure drop during oscillation. The thermo-acoustic oscillation was more pronounced at a lower mass flux, lower pressure, or higher heat flux. The instability disappeared when the inlet bulk temperature exceeded a threshold value. A dimensionless criterion was obtained to evaluate the stability limit of thermal-acoustic oscillation.

*n*-Dodecane (C12) and decalin (decahydronaphthalene, DHN) were studied as model alkane and cycloalkane compounds, respectively. Pyrolysis of C12, DHN, and C12-DHN binary fuels with different mass ratios of C12 to DHN was performed on an experimental cracking apparatus equipped with a tubular reactor under supercritical conditions (3.5 MPa and 973 K = 700 °C) [34]. The amount of coke deposited on the inner surface of the tubular reactor was determined by weight. During a study of the effects of endothermic hydrocarbon fuel composition on the pyrolysis and anti-coking performance, it was observed that there were reciprocal inhibition and competition effects during the co-pyrolysis of C12 and DHN. Increasing the ratio of C12 to DHN exerted a positive effect on gas yields of endothermic hydrocarbon fuels, but hardly influenced the selectivities of H<sub>2</sub> and alkenes (≤ C<sub>4</sub>). The heat sink abilities of the endothermic hydrocarbon fuels depended largely on the gas yields, representing the thermal cracking level. The C12:DHN ratio greatly affected the amount of coke and the morphologies of the endothermic hydrocarbon fuels. The

alkane:cycloalkane ratio for advanced EHF's should not be less than 3/7 in order to minimize coking problems.

## 2.2.2 Safety Properties of Hydrocarbon Fuels

### 2.2.2.1 Flash Points of Hydrocarbon Fuels

Flash points of flammable liquids are determined in accordance with ASTM D 92–98a [35], ASTM 1998 (open cup) or ASTM D93 [36], ASTM 1993 or ASTM D3828 [37], ASTM 1994 or ASTM D56 [38], ASTM 1993 (closed cup) or ASTM D1310 [39], and ASTM 1993 (open cup). See also [40].

### 2.2.2.2 Autoignition Temperatures of Hydrocarbon Fuels

Autoignition temperatures of flammable liquids are determined in accordance with ASTM Method E659–78 (1994) [41]. An increase in molecular weight results in a decrease in spontaneous ignition temperature for both normal alkanes and normal alkenes. The spontaneous ignition temperatures for normal alkanes decrease with increasing molecular weight from 778 K (504 °C = 940 °F) for propane to 503 K (230 °C = 446 °F) for hexadecane (Table 2).

**Table 2:** Spontaneous ignition temperatures of *n*-alkanes.

| Hydrocarbon | Spontaneous ignition temperature |     |     | Time lag at last ignition |
|-------------|----------------------------------|-----|-----|---------------------------|
|             | K                                | °C  | °F  | min                       |
| Propane     | 778                              | 504 | 940 | 0.1                       |
| Butane      | 704                              | 431 | 807 | 0.1                       |
| Pentane     | 558                              | 284 | 544 | 0.4                       |
| Hexane      | 534                              | 261 | 501 | 0.5                       |
| Heptane     | 520                              | 247 | 477 | 0.5                       |
| Octane      | 513                              | 240 | 464 | 0.9                       |
| Nonane      | 507                              | 234 | 453 | 1.1                       |
| Decane      | 505                              | 232 | 449 | 0.9                       |
| Hexadecane  | 503                              | 230 | 446 | 1.1                       |

Data source: [42]

In general, increased branching increases the ignition temperatures of alkanes and alkenes. Aromatics have considerably higher spontaneous ignition temperatures than most alkanes or alkenes, with benzene having the highest value for any of the hydrocarbons tested [42]. The spontaneous ignition temperature of a substance has been defined as the lowest temperature at which that substance will ignite in air or oxygen without the application of an external source of ignition. Spontaneous ignition temperatures of fuels are of some significance in the performance of reciprocating engines

because, in general, fuels for spark-ignition engines should have high ignition temperatures and fuels for compression-ignition engines should have low spontaneous ignition temperatures. Rocket engines can operate with fuels with a wide range of autoignition temperatures. The spontaneous ignition temperature is a factor in rating the inflammability hazards in the handling of hydrocarbon fuels during their production, transportation, storage, and use as rocket fuels.

In another test series in a crucible apparatus, the spontaneous ignition temperature of hexadecane with dropwise addition was 505 K (232°C), and with spray injection it was 503 K (230°C) [43].

The autoignition temperature of an undecomposed endothermic fuel is an important safety criterion. The autoignition temperature of a decomposing endothermic fuel changes with progressing endothermic decomposition. The autoignition temperatures and ranges of flammability of hydrocarbons and other combustibles must be known when investigating fire and explosion accidents [44].

In order to study the importance of fuel cracking in the autoignition of endothermic fuel/product mixtures, both the autoignition temperatures and the ignition delay times of the hydrocarbon vapors and their endothermic pyrolysis products in air were studied in a shock tube [45]. The ignition delays of ethene and heptane, typical constituents of a reformed fuel, and simulated endothermic fuel products were measured in diluted air/fuel mixtures behind reflected shock waves at temperatures in the range 1100–1400 K, pressures of 5–8 atm, and equivalence ratios of 0.5 and 1.0. The experimental data were compared to literature-sourced correlations for pure hydrocarbons and hydrogen, and new ignition delay correlations were derived from the combined data sets and expressed as Arrhenius equations for each fuel mixture. The relative ignition delay times for the different fuels decreased in the order methane > heptane > reformed endothermic fuel > ethylene > hydrogen. These results support the general assumption that fuel cracking enhances ignition. However, autoignition of the endothermic reaction product mixture was not driven entirely by that of the constituent with the shortest ignition delay (i.e., ethylene or hydrogen). Small changes in the concentrations of the individual component species were not likely to cause large changes in the ignition delay time of the fuel.

The ignition temperatures of hydrocarbons can be lowered in the presence of heterogeneous or homogeneous catalysts. Homogeneous catalysts are soluble in kerosenes. For instance, a certain catalyst produced substantial improvements in combustion activity for both JP-10 and a surrogate, JP-5 [46]. The addition of only 5 ppm catalyst to the surrogate JP-5 reduced the temperature required to initiate combustion by about 300°C. These results demonstrate that a soluble catalyst has the potential to significantly reduce the ignition delay and to widen the range of stable flame operating conditions.

### 3 Production of Hydrocarbon Fuels

The primary source of hydrocarbon fuels is petroleum from crude oil. Petroleum is subjected to fractionated distillation in tall distillation columns. The fractions are characterized by their boiling ranges. The heavy residues from crude oil distillation are then cracked or hydro-cracked to create more of the more desirable lighter boiling fractions. Only a small percentage of synthetic hydrocarbon fuels is produced from natural gas or coal, or, more recently, from biomaterials (wood, grass, oily fruits, spent cooking oils).

The importance of the availability of hydrocarbon fuels and the impact of temporary shortages of these fuels on the automotive, air, and sea transportation economy have been well documented. A large proportion of petroleum fuels is used as heating oil, so it is just burned for its heating value – a very wasteful practice considering that we could be using clean nuclear energy instead. Hydrocarbons are much more difficult to replace as a feedstock for the chemical industry in the production of plastics, clothing, fertilizer, and pharmaceuticals than as heating oils, so the remaining fossil hydrocarbons should be reserved for use in the chemical industry and as rocket propellants.

#### 3.1 Purification of Hydrocarbon Fuels

The thermal stability of Jet A-1 fuel subjected to purification by clay treatment, desulfurization, or hydrogenation was determined in comparison to the untreated fuel using the Jet Fuel Thermal Oxidation Tester (JFTOT) thermal stability method [47]. Desulfurization increased the JFTOT breakpoint by 66–77 K, and desulfurization followed by hydrogenation increased the JFTOT breakpoint of the fuel by more than 83 K. A low-aromatic JP-4 type of fuel blended from a hydrogenated stock and a solvent-treated stock to remove aromatics was also tested and compared to a conventional JP-4 fuel. Desulfurization, hydrogenation, clay treatment, and aromatic solvent extraction were shown to be effective methods for upgrading the thermal stability of kerosene fuels.

# Hydrogen

## Hydrogen

Thanks to its low molecular mass and high heat of combustion, hydrogen, typically liquid hydrogen, makes an excellent rocket propellant fuel. It is of interest and very educational to study the historical evolution of hydrogen as a rocket propellant, and therefore many older references are included in this book. In some respects this book is a book on the history of rocket propellants. Today's achievements in space travel would not be possible without the use of liquid hydrogen. In the following discussion, we'll frequently abbreviate liquid hydrogen as LH2 or LH<sub>2</sub>.

There were many sources of information on liquid hydrogen, most of those from the Cryogenics Laboratory in Boulder, CO, USA, operated by the National Bureau of Standards. Many of those references are now included in the current chapter on hydrogen, although some are already quite old.

To be accurate, the molecular hydrogen we use as a rocket fuel should be called dihydrogen in order to differentiate it from atomic hydrogen, which is also a potential rocket fuel but difficult to stabilize and store. In the following chapters, it is safe to assume that whenever a fuel is described as hydrogen that this is **dihydrogen** and not atomic hydrogen. It would be nice if we could add a chapter on atomic hydrogen as a rocket propellant, because that would be the most energetic rocket propellant we can imagine. Unfortunately, atomic hydrogen is difficult to store and it will be a long time before we can master it [1]. Another form of hydrogen we would dearly like to have in quantity and fly it in our rockets is metallic hydrogen. Again, it exists only in other worlds and if we can create it on Earth, it is only in tiny quantities and only for a short time.

Initially many technical obstacles prevented the application of liquid hydrogen as a rocket propellant [2]. Only few people were optimistic enough that it could ever be used as a transportation fuel. When the first edition of a book on rocket propellants went to press in 1968, only few upper stages had ever flown with liquid hydrogen. Now there are many books describing the history of the evolution of liquid hydrogen as a rocket propellant. The first CENTAUR upper stage was launched atop an Atlas booster in May 1962, and not all initial flights were successful [3]. Much progress was made by the time liquid hydrogen in the SATURN-V S-II second stage and S-IVB third stage enabled the APOLLO astronauts to reach the moon. The largest rocket ever to use liquid hydrogen was the ENERGIYA, the core stage of which had a lift-off mass of 905 tons and a dry mass of 85 tons, which contained 117 metric tons of liquid hydrogen at launch, even more than the Space Shuttle (103 tons) or ARIANE-V core stage (25 tons) or H-II core stage (14.5 tons) or DELTA-IV Heavy (28.5 tons in the first stage and 4.2 tons in the second stage). As of 2013, there were plans that Russia may revive the ENERGIYA launch vehicle to use it again for launching components for the next space station

into orbit. The US Space Launch System core stage, a derivative of the Space Shuttle external tank, will contain 144 tons ( $2033 \text{ m}^3 = 537000$  gallons) of liquid hydrogen.

First attempts to liquefy hydrogen using the same technique as for liquid air or liquid oxygen were wrought with difficulties. For one, hydrogen has a negative Joule-Thomson coefficient such that when compressed hydrogen expands isentropically at room temperature, it warms up instead of cooling down. Then, even after a jug full of liquid hydrogen has been obtained by precooling the gas before expanding it, the liquid will suffer evaporation losses due to the exothermic orthohydrogen-parahydrogen ( $o\text{-H}_2 \rightarrow p\text{-H}_2$ ) conversion, which continues at an unslowable rate, thanks to quantum mechanics [4]. This can be avoided by accelerating the conversion and aiming at complete orthohydrogen→parahydrogen conversion already during the stepwise liquefaction process (section “Catalysts for Orthohydrogen-Parahydrogen Conversion”).

Only history fans will find useful bits of information in the long list of publications that we referenced in the first edition of a book on rocket propellants. Most of these documents that were relatively new in 1968 are now hopelessly out of date because liquid hydrogen technology development in the second half of the last century moved much faster than even the most optimistic observers dared to hope for at mid-century of the 1900s. There were even voices of some pessimists who considered it impossible to use liquid hydrogen as a rocket propellant [5].

The early development of large-scale liquefaction and application of hydrogen as a rocket propellant was driven not only by its anticipated use as a chemical rocket fuel in combination with suitable oxidizers, but also by the demonstration of its use as a working fluid for nuclear thermal rockets and arcjets, plasma rockets, and magnetohydrodynamic rockets [6]. Table 1 contains a historical summary of publications on hydrogen as a working fluid for nuclear thermal rockets. This includes the KIWI-A, ROVER, and the NERVA nuclear thermal rocket projects, which are now only part of by-gone history.

**Table 1:** Historical descriptions of liquid hydrogen use in nuclear thermal rockets.

By the early 1970s, NASA had ground-tested a series of nuclear thermal rocket engines at the Nevada test site. These systems generated up to 4500 megawatts of thermal power, produced 1.1 million Newtons ( $1.1\text{MN} = 250000$  pounds force) of thrust, about half the thrust of a space shuttle main engine, and accumulated 90 min of run time. Unfortunately, this promising NERVA, for Nuclear Engine for Rocket Vehicle Application, space propulsion system was discarded during the agency's precipitous post-APOLLO downsizing. Liquid hydrogen technology that was developed during these programs greatly benefited the later development of LOX/LH2 bipropellant rocket engines. One can only speculate if this nuclear thermal rocket technology will ever be revived to play a role in future rocket propulsion.

NASA awarded a contract in 2017 with the nuclear engineering firm BWXT to examine design and licensing requirements for a full-scale, full-thrust ground test of a nuclear thermal propulsion engine along the lines of the NERVA tests 50 years ago [14]. The US \$18.8 million contract included the conceptual design of a propulsion reactor that, because of its much higher rocket exhaust velocity, would be about twice as efficient as chemical rockets such as the LOX/hydrogen space shuttle main engine. Such a 500-megawatt (a measure of reactor power) nuclear thermal rocket might have a low-enriched uranium core to alleviate proliferation security concerns and ceramic/metallic fuel elements to deliver a specific impulse of 900–910 s.

Here we deal only with chemical rocket propellants, but hydrogen is a major player in both chemical and other rockets. In nuclear research, liquid hydrogen is used for bubble chambers, neutron moderators, and superconductors [15].

In the far distant future, hydrogen or deuterium could also be the fuel of choice for fusion nuclear reactors and fusion rockets. In the meantime, in the area of air-breathing engines, liquid hydrogen as a fuel in supersonic combustion scramjets has moved from the stage of computation and ground testing to the first flight demonstration in the X-43A in 2004. It is also being considered as a fuel for commercial passenger jet transports where it is used as fuel in fuel cells to generate electricity and electric motors drive the propellers [16]. Compressed hydrogen/air or liquid hydrogen/air fuel cells are advancing to the stage that they will be used in prototype automobiles and experimental airplanes with electric motors.

Automobiles operating on combustion engines fed with compressed hydrogen gas are already in use in several demonstration projects and promise a future free from hazardous emissions. Automobiles with liquid hydrogen storage have been considered, but of course safety considerations will prevent such an application for now [17]. We realize that not every person with a driver's license is a rocket engineer, and they might have difficulty in safely managing the fueling and the boil-off during idle periods. Supercritical oxygen and hydrogen storage was used to supply fuel cells on the APOLLO Service Module and on the Space Shuttle Orbiters, but that technology is also not suitable for the average consumer.

Liquid hydrogen technology borrowed from the space program is aiding the development of earth-based hydrogen-powered airplanes. Liquid hydrogen already powers fuel cells in electrically driven propeller airplanes. In 2013, a fuel-cell-powered unmanned aerial vehicle (UAV) developed by the US Naval Research Laboratory (NRL), *Ion Tiger*, flew 48 h using liquid hydrogen fuel in a new, NRL-developed, cryogenic fuel storage tank and delivery system. The liquid hydrogen-fueled *Global Observer* UAV made by AeroVironment can fly at 65000 ft for more than 1 week, letting it operate as a geosynchronous “satellite” system for regional communications coverage. A Fuel Cell Demonstrator Airplane is being developed by Boeing Research and Technology Europe in Madrid, Spain. *Phantom Eye* is a liquid hydrogen-fueled, high-altitude, and long-endurance unmanned aircraft system for persistent intelligence, surveillance, reconnaissance, and communications missions. The demonstrator aircraft is capable of maintaining its altitude for up to 4 days while carrying a 450-pound payload. Typical payloads include multiple sensor packages for monitoring, tracking, and communications. A full-size *Phantom Eye* variant is designed to stay aloft for up to 10 days and carry a payload of 2000 pounds.

## 1 Occurrence, Production, and Liquefaction of Hydrogen

### 1.1 Occurrence of Hydrogen

Weight-wise and the number of atoms-wise, hydrogen is the most abundant element of the universe (as we know it). It has been estimated that 75% of the cosmos consists of hydrogen. Our sun consists of about 84% hydrogen, and much of it will be converted to helium as the aging of our sun progresses. This thermonuclear process is the source of life-sustaining energy on our planet Earth. On Earth, hydrogen rarely occurs in elemental form. It mostly occurs in the form of water, mineral hydrates, and a precious small fraction occurs in the form of petroleum and natural gas (methane). The top-most crust of the Earth to a depth of 16 km contains about 0.88 mass-% hydrogen. The atmosphere at sea level contains hardly any dihydrogen gas. The upper reaches of the ionosphere contain a little dihydrogen and atomic hydrogen that is likely to escape Earth once it becomes accelerated or ionized by solar wind. A distant cloud of hydrogen atoms that makes up the outermost part of Earth's atmosphere extends up to 630000 kilometers (391464 miles) away, far enough to envelope the moon.

On Earth, hydrogen gas may form along with methane as the result of microbial decay of organic material. Fermentation gas accumulations and mixtures with air have been the cause of numerous fires and explosions.

It has been theorized that on Jupiter, where interior pressures are millions of atmospheres, hydrogen may exist as a super-hot liquid metal. The density of metallic hydrogen is expected to be about ten times that of liquid H<sub>2</sub> at Earth atmospheric

pressure, which translates into great energy density, and metallic hydrogen would be a powerful propellant if we could tame it. In March 1996, the Lawrence Livermore National Laboratory (LLNL) observed the formation of metallic hydrogen at 1.4 megabars pressure (an unanticipated result of using a gas gun to compress liquid hydrogen). It is not known if metallic hydrogen could be stabilized long enough to be used as a solid rocket propellant ingredient at ambient pressure and temperature. Methods of using metallic hydrogen have been proposed, including entrapment in solid hydrogen, or suspended in a liquid cryogen like liquid helium [18].

## 1.2 Production of Hydrogen

### 1.2.1 Production of Hydrogen from Carbon-based Fuels

Hydrogen is mostly prepared by steam reforming of natural gas [19]:

or partial combustion of natural gas

or other hydrocarbons

In earlier years, in a coal-based instead of oil-based economy, industrial hydrogen production, e.g. for the synthesis of ammonia, was often done by first producing synthesis gas (“water gas”) by passing overheated steam over coal (coke)

or

and then shifting the CO equilibrium in the water gas shift reaction

to a point where the carbon dioxide could be washed out and separated from unreacted CO and the desired H<sub>2</sub> product.

Hydrogen production by electrolysis of water is very energy-intensive and would be economical only in locations where due to cheap hydropower the off-peak capacity of the generating plant can be used to produce hydrogen. Often this electrolysis process is combined with isotope separation and production of deuterium and heavy water. Hydrogen gas is often a by-product of other industrial processes, such as the chlorine-alkali electrolysis.

### 1.2.2 Thermochemical Water Splitting Cycles

Thermochemical water splitting cycles, mostly based on solar energy, have been developed but have not advanced past the feasibility demonstration stage, [20–27]. It is possible to use solar heat directly to split  $\text{H}_2\text{O}$  into  $\text{H}_2$  and  $\text{O}_2$  or  $\text{CO}_2$  into  $\text{CO}$  and  $\text{O}_2$ . Such processes would be of interest for *in situ* resource utilization, producing propellants, and life-support on other planets or moons from indigenous resources; however, these single-step processes require operating temperatures above  $2000^\circ\text{C}$ , which places high demands on materials and process conditions. Alternative multi-step thermochemical cycles operate at lower temperatures and eliminate the need for high-temperature gas separation [28].

## 1.3 Liquefaction of Hydrogen

The first person to produce liquid hydrogen was Sir James Dewar in 1898. In the literature, liquid hydrogen may occasionally also be called “liquefied hydrogen.”

The ideal work required for liquefaction of normal hydrogen ( $n\text{-H}_2$ ) starting at 300 K and 101.3 kPa is 12019 kJ/kg (5167 BTU/lb). Conversion to parahydrogen requires additional energy. There are several other hydrogen liquefaction processes, but the Claude cycle is the only one of practical interest [29]. Large hydrogen liquefaction plants usually operate with multi-stage turbo compressors and turbine expanders [30, 31].

The hydrogen gas to be liquefied must be carefully purified and freed of all contaminants which might solidify at the temperature of liquid hydrogen and clog the apparatus. Carbon monoxide and nitrogen, which might still be present in the feed as residues from the steam reforming process, must first be removed. They could be condensed in a cold trap that is cooled with cold hydrogen in a separate circuit. Other contaminants are removed by washing the gas with liquid methane. Residual contaminants are removed by absorption on a bed packed with activated charcoal, silica gel or molecular sieves. That will reduce the contaminant concentration in the hydrogen to below 1 ppm by volume.

Not all liquid hydrogen is alike. In the freshly condensed state, without ortho-hydrogen-parahydrogen conversion during liquefaction, the normal hydrogen liquid would consist of a mixture of orthohydrogen and parahydrogen in a molar ratio of 3:1. This liquid is sometimes called normal hydrogen. Orthohydrogen contained in the normal hydrogen mix would slowly convert to parahydrogen and release the heat of conversion. This heat of orthohydrogen-parahydrogen ( $o \rightarrow p$ ) conversion would result in excessive evaporation losses from the vessel containing the liquid if one attempted to store normal hydrogen as a liquid. The heat of conversion ( $1411\text{ J/mol} = 337.2\text{ cal/mol}$ ) is 1.562 times bigger than the heat of evaporation of liquid hydrogen ( $903\text{ J/mol} = 215.9\text{ cal/mol}$ ), such that for every kg of orthohydrogen that converts,

1.562 kg of liquid hydrogen is lost. For quantum mechanical reasons, there is no pure orthohydrogen. Figure 58 (shown later in Section 5.4.1) illustrates the evaporation losses as a function of the initial orthohydrogen content in the freshly liquefied mixture.

In order to achieve the equilibrium composition corresponding to the momentary temperature and pressure, and in order to accelerate the rate at which the equilibrium is attained, the hydrogen gas is repeatedly passed over catalysts during the cooldown on its way to being liquefied. Catalytically active for this conversion are all paramagnetic materials. A paramagnetic catalyst can reverse the nuclear spins without breaking the H–H bonds. As a matter of fact, a test for paramagnetism in certain solids uses the rate of *o* – *p* conversion of natural cold hydrogen as an indication of the extent of paramagnetism in the sample. Active catalysts consist of chromium(III) oxide deposited on alumina, iron(II, III) oxides and oxygen adsorbed on activated charcoal. There are three conversion strategies, and they differ in the energy requirements during liquefaction:

1. Continuous conversion
2. Stepwise conversion initially at 65 K (typically achieved by lowering the pressure above a bath of LN<sub>2</sub>) and then completing the process at 20.4 K
3. Performing all conversion at 20.4 K

The production of liquid parahydrogen requires more energy than the production of liquid normal hydrogen. While the production of normal hydrogen requires typically 3.35 kWh/kg, the production of parahydrogen with only a trace (0.21%) of residual orthohydrogen requires the energy listed in Table 2, depending on the cooldown and equilibration sequence

**Table 2:** Energy requirements for hydrogen liquefaction.

|          | kWh/kg | kWh/L | Relative energy consumption, %, relative to Method 1 = 100% |
|----------|--------|-------|-------------------------------------------------------------|
| Method 1 | 3.9    | 0.28  | 100                                                         |
| Method 2 | 4.7    | 0.33  | 117                                                         |
| Method 3 | 5.3    | 0.38  | 137                                                         |

The energy consumption for liquefying hydrogen is much higher than that for liquefying air or oxygen. One can only appreciate the current advanced state of liquid hydrogen technology if one goes back and reads some of the historical references, written at a time when the scale of current liquid hydrogen operations could not be imagined [32–35]. Then, during the 1960s, liquid hydrogen technology slowly began to evolve [36].

With an average hydrogen feed of 150 ton/day, a cascade mixed refrigerant (CMR) precooling process with implemented chillers and integrated liquid expanders was predicted to be the most energy-efficient and exergy-efficient process, with an exergy efficiency calculated as above 45% [37].

The design of a proposed liquid hydrogen plant using a multi-component refrigerant (MR) refrigeration system capable of producing 100 tons of liquid hydrogen per day was analyzed [38]. The MR system can be used to cool feed normal hydrogen gas from 298 K (25 °C) to the equilibrium temperature of 80 K (−193 °C) with a high efficiency. For the transition from the equilibrium temperature of the hydrogen gas from 80 to 20 K (−193 to −253 °C), a four-stage H<sub>2</sub> Joule-Brayton cascade refrigeration system was recommended. The overall power consumption of the proposed plant was predicted to be 5.35 kWh/kg LH<sub>2</sub>, with an ideal theoretical minimum of 2.89 kWh/kg LH<sub>2</sub>. Thus, it could represent a plant with the lowest construction cost with respect to the amount of liquid hydrogen produced in comparison to today's plants, e.g., those in Ingolstadt and Leuna in Germany.

Today's hydrogen liquefiers are a mature technology for capacities up to 30 ton/day and with energy requirements of 30–40 MJ/kg LH<sub>2</sub>, while the world's capacity today is around 350 ton/day, which is an order of magnitude lower than the required capacity for fueling a future vehicle mobility largely based on hydrogen. Diverse investigations indicated that liquefier capacity as high as 900 ton/day as well as energy requirements as low as 18–25 MJ/kg may be achieved [39, 40].

### 1.3.1 Theory of Hydrogen Liquefaction

Most gases at ambient temperature are cooled by adiabatic expansion from high to low pressure. Hydrogen behaves differently. The temperature of hydrogen increases when it is expanded at a temperature and pressure outside the range of temperature and pressure conditions that define the Joule-Thomson inversion curve for hydrogen. The maximum inversion temperature for hydrogen is 202 K (−71 °C = −96 °F) at an absolute pressure of zero. At any temperature and pressure condition greater than this, the temperature of hydrogen will increase upon expansion.

Hydrogen cannot be liquefied like other permanent gases (air, nitrogen, oxygen) by the conventional LINDE liquefaction scheme because at room temperature it has a negative differential Joule-Thomson coefficient. The Joule-Thomson coefficient increases with decreasing temperature and reaches the value of zero at the inversion temperature of hydrogen, which is at 202 K. If one wants to liquefy hydrogen by compressing, cooling, and expanding it, one must first pre-cool the gas to below the inversion temperature. In most cases the hydrogen is pre-cooled in a heat exchanger with liquid nitrogen which takes it sufficiently below the inversion point.

The Joule-Thomson coefficient,  $\mu$ , is defined as

$$\mu = -C_P^{-1} \left( \frac{\partial H}{\partial P} \right)_T = \left( \frac{\partial T}{\partial P} \right)_H$$

The sign of  $\mu$  indicates whether a sudden gas expansion will cause an increase or decrease in the temperature of the gas. If  $\mu$  is positive, the expanding gas will be cooled. The locus of points where  $\mu = 0$  is called the Joule-Thomson inversion curve. This curve for parahydrogen is illustrated in Figure 1.

**Figure 1:** Joule-Thomson inversion curve for parahydrogen gas. (Reproduced and modified from [41].)

Values of the Joule-Thomson coefficient were calculated from compressibility isotherms for pressures up to 253 MPa (2500 atm) [42, 43]. The data were presented at integral values of pressure and temperature for the normal ortho-para concentrations.

The equations of state pressure-volume temperature (PVT) relations for hydrogen and several other gases were used to establish Joule-Thomson inversion curves for each fluid [44]. The principle of corresponding states was applied to the inversion curves, and a generalized inversion curve for fluids with small acentric factors was developed. The critical isenthalpic Joule-Thomson coefficient  $\mu_c$  was determined and a simplified approximation

$$\mu_c \approx \frac{T_c}{6P_c}$$

was found adequate, where  $T_c$  and  $P_c$  are the temperature and pressure at the thermodynamic critical point. The maximum inversion temperatures were obtained from the second virial coefficient (maximum  $B/T$ ).

### 1.3.2 Design of Hydrogen Liquefaction Plants

Liquefaction of hydrogen is a multi-step process as illustrated in Figure 2.

### 1.3.3 Catalysts for Orthohydrogen-Parahydrogen Conversion

In order to avoid evaporation losses due to orthohydrogen-parahydrogen conversion in the freshly liquefied hydrogen, the  $o \rightarrow p$  conversion must be achieved as close to the equilibrium composition as possible. The liquefaction is usually a multi-step process and each stage has its own catalytic converter [46]. Of the many parameters which must be considered in the design of an efficient orthohydrogen-parahydrogen converter, the most obvious is the choice of an effective catalyst. After this choice is made, there remain as variables the conditions of temperature, pressure, feed composition and space velocity (or contact time) under which the conversion proceeds. All these variables influence the kinetics of the conversion [47, 48]. Basically, any paramagnetic material will catalyze the  $o \rightarrow p$  conversion, but for an industrial installation, more active catalysts especially developed for this purpose are being used.

The  $o \rightarrow p$  conversion was investigated on a series of  $\text{Cr}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalysts by a static method at 77K and under various pressures in the gaseous and liquid states [49]. Chromia-alumina catalysts containing 1–2 mass-%  $\text{Cr}_2\text{O}_3$  on alumina were faster than commercial catalysts containing 20–35%  $\text{Cr}_2\text{O}_3$  [50]. The kinetics of the  $o \rightarrow p$  conversion is a first-order process and the rates of conversion depend on diffusion into and out of the pores of the catalyst [51]. The overall liquefaction cycle efficiency depends on efficient utilization of  $o \rightarrow p$  conversion catalysts [52].

Kinetic rate measurements were made of the low-temperature  $o \rightarrow p$  conversion reaction with a very active  $\text{NiO-SiO}_2$  catalyst [53]. The model matched experimental data over the temperature range 79–93K (142–168°R) and pressure range 0.69–10.3 MPa (100–1500 psia).

**Figure 2:** Hydrogen Liquefaction Process Flowchart. (Reproduced from [45] with permission from Linde 9 Feb 2021.)

Chromium(VI) oxide ( $\text{CrO}_3$ ) supported by silica gel is a highly efficient catalyst for ortho-para conversion at low temperatures [54]. The material is also less susceptible to poisoning than the commonly used ferric hydroxide gels.

### 1.3.4 Hydrogen Purification

Any gas other than helium as a contaminant in the hydrogen feed stock will interfere with the liquefaction process because the foreign gas would condense as solid crystals and clog orifices in the process equipment. Nitrogen can be removed by adsorption onto silica gel at low temperatures [55]. The adsorbed nitrogen would also inhibit the catalysts that are needed for  $o \rightarrow p$  conversion [56]. Any adsorbate which competes with hydrogen may be expected to reduce the catalyst effectiveness unless this competing adsorbate is also a catalyst.

One must avoid the formation of oxygen/hydrogen mixtures under any circumstances. Solid oxygen floating in liquid hydrogen will clog orifices and constitutes an explosion hazard. The specific concern is with the behavior of oxygen which is present as a trace impurity (concentration of a few parts per million) in a high-pressure hydrogen stream which is being cooled and liquefied. Oxygen crystallizes during the cooling process when the saturation concentration of oxygen is reached. The exact temperature depends upon the total pressure and the oxygen concentration. For low concentrations, the temperature is below the triple point temperature of oxygen ( $54.37\text{ K} = -218.78\text{ }^{\circ}\text{C} = -361.8\text{ }^{\circ}\text{F}$ ) [57]. The possibility always exists that solid oxygen may concentrate in heat exchangers and other process components which are at temperatures lower than the triple point. Even at very low concentrations, the oxygen may accumulate and cause hazardous conditions. The data on the solid/vapor equilibria of the oxygen/hydrogen system are important for the safe design and operation of hydrogen liquefaction equipment. Trace oxygen in hydrogen feed could be converted to water by first passing the gas mixture over a platinum catalyst and then water would be easier to remove and would not constitute an explosion hazard.

### 1.3.5 Hydrogen Liquefaction Capacity in the World

Table 3 shows a list of some of the hydrogen liquefaction plants in use around the world. Most of the liquid hydrogen plants are stationary, but there are also mobile hydrogen liquefaction machines [58].

The size and liquefaction and storage capacity of these liquid hydrogen production facilities continues to increase [40]. Using isentropic instead of isenthalpic expansion processes, cascading of refrigerating cycles, use of mixed refrigerants as working fluid of refrigeration cycles, and hybridization of renewable energy power cycles to refrigeration cycles are the main growing approaches in the large-scale hydrogen liquefaction market.

**Table 3:** Commercial hydrogen liquefaction plants worldwide.

#### 1.3.4.1 Hydrogen Liquefaction Capacity in the USA.

As of 2003, there were already 10 hydrogen liquefaction plants in North America. Train size ranged from 6 to 35 tons per day (TPD, 5400–32000 kg/day) [45]. In 1960, the first few liquid hydrogen plants were built to support the APOLLO program. In the beginning of the 1960s there was a liquid hydrogen demand for US space programs. The capacity installed up to 1965 was capable of supplying the demand of NASA and others until 1977. In this period, no additional plants were built, not least because of the reduction of NASA's space activities. Since 1977, further increase in capacity this time was mainly caused by the steadily increasing commercial demand for liquid hydrogen. As of 2015, there were more than 9 hydrogen liquefaction plants in the US with production rates of 5–34 tons per day (TPD). As of 2005, the Air Products plant at New Orleans had a liquefaction capacity of 54 metric tons/day and was considered the largest plant of its type in the world.

As of 2005, one of the plants operated by Air Products in Sacramento had a capacity of 5.4 metric tons/day and a storage capacity of 36 tons. Much of that hydrogen at that time was used in the semiconductor industry. Air Products supplies the largest quantity of liquid hydrogen in North America, followed by Praxair. As of 2009, Praxair had 5 hydrogen liquefaction plants in the US with production rates between 6 and 35 TPD LH<sub>2</sub>. Typical specific power consumptions were between 12.5 and 15 kWh/kg LH<sub>2</sub> [45].

A historical review of the development of large-scale hydrogen liquefaction processes throughout the world from 1898 to 2009 included a literature review, designs and a list of the capacity and location of every hydrogen liquefaction plant in the world [59]. It was found that every current hydrogen liquefaction plant is based on the precooled Claude system, which is still the same as was 50 years ago with little improvement. Redesigning of hydrogen liquefaction plants is done with the target of efficiencies of 40–50% and lowering energy usage of 10 kWh/kg LH<sub>2</sub> to around 5 kWh/kg LH<sub>2</sub>. This leads to predictions about the development and improvement potential of future large-scale liquid hydrogen liquefaction plants. Methods to resolve the challenges of the future plants include proposing completely new configurations and efficient systems coupled with improved efficiencies of the main system components, such as compressors, expanders, and heat exchangers. Hydrogen liquefaction plants would best be located at places where LNG tankers are off-loaded and the LNG is gasified for distribution to the pipeline network, because then the cold from the liquid LNG can be used to pre-chill the GH<sub>2</sub> to be liquefied.

#### 1.3.4.2 Hydrogen Liquefaction Capacity in Europe

As of 2009, there were 4 hydrogen liquefaction plants in Europe with capacities of 5–10 TPD, and 11 plants in Asia with capacities of 0.3–11.3 TPD. In 1987 L'Air Liquide started operation of a 5.4 metric tons/day liquefaction unit at Rozenburg in The Netherlands and a 10 metric tons/day unit at Waziers in North France. Up until that time, liquid

hydrogen was available only from a 1 ton/day plant at Fraiss-Marais near Waziers. The Rozenburg facility has 70-ton storage capacity.

An example of a modified precooled Claude cycle is the hydrogen liquefaction plant in Ingolstadt near Munich, Germany, which has been in operation since 1992 [60]. The liquefier has a daily liquefaction capacity of 4.4 tons and is based on a Claude process with nitrogen precooling. Apart from the liquefier, the whole plant comprises a pressure-swing adsorption purification, a high-pressure hydrogen compressor station, a  $\text{LH}_2$  storage tank and filling stations for  $\text{GH}_2$  and  $\text{LH}_2$  trailers.

Linde opened a second hydrogen liquefaction plant in September 2007 in Leuna, Germany. As of 2009, it was the newest and largest  $\text{H}_2$  liquefier plant in Germany. The energy consumption of the Leuna plant was less than 14 kWh/kg  $\text{LH}_2$ .

## 2 Physical Properties of Hydrogen

### 2.1 The Orthohydrogen/Parahydrogen Equilibrium

The two ortho-para isomers of hydrogen have substantially different physical properties. Therefore, when physical properties are listed, one must specify if this property is for the equilibrium mixture at one particular temperature ("normal hydrogen" at room temperature) or for parahydrogen at its normal boiling point. The difference of physical properties of hydrogen is caused by the different orientation of spin in the two hydrogen atom nuclei that form the dihydrogen  $\text{H}_2$  molecule. The difference between orthohydrogen and parahydrogen is the relative orientation of the nuclear spin of the individual atoms. The nuclear spin is associated with the rotational motion of the nuclei about an axis perpendicular to the molecular axis (the line between the two atoms), and the spins in the two atoms forming the hydrogen molecule may be in the same direction (parallel), or in opposite directions (anti-parallel). The spin orientation relative to the individual nuclei of the molecule has a significant influence on the energy levels of the molecule. This would also occur with heavier atoms and molecules, but it is most noticeable with hydrogen. There are quantum numbers for the spin and the corresponding energy levels. The molecules with anti-parallel nuclear spins, called parahydrogen, have even rotational quantum numbers ( $J = 0, 2, \dots$ ) and are in the lowest energy states. The molecules with parallel nuclear spins, called orthohydrogen, have odd quantum numbers ( $J = 1, 3, \dots$ ) and are predominant at higher temperatures. The energy content of the two orientations is different, with the anti-symmetric being the lower state of energy. In parahydrogen the two spins are anti-symmetric, in orthohydrogen the two spins are parallel. Because of the low molecular mass of dihydrogen this quantum chemical effect causes observable differences in physical properties. Similar ortho-para isomerism occurs also in hydrogen isotopes such as deuterium, but it is not as pronounced as in dihydrogen itself. The ortho-para equilibrium is temperature dependent (Figure 3).

**Figure 3:** Ortho-para-hydrogen equilibrium as a function of temperature. (Reproduced and modified from [41].)

Measurements and quantum mechanical calculations show that normal hydrogen at room temperature consists of a mixture of orthohydrogen and parahydrogen in the mol ratio of 3:1. The equilibrium composition is temperature dependent. The equilibrium shifts toward the less energetic parahydrogen when the temperature is lowered. At the normal boiling point of hydrogen at 20.4 K, the equilibrium mixture contains only a small residual of 0.3% orthohydrogen. The effect of pressure on these equilibrium concentrations is considered to be negligible.

At high temperatures above room temperature one does not obtain pure orthohydrogen. The normal hydrogen at higher temperatures always contains a mixture of orthohydrogen and parahydrogen (Table 4).

Hydrogen physical properties can be divided into two groups; the first group of properties exhibits relatively large changes in value between orthohydrogen and parahydrogen [62]. The second group of properties exhibits only very small changes in value, if any, with differences in ortho-para concentration. The properties with significant ortho-para dependency include specific heat and properties related to specific heat, such as entropy, enthalpy, thermal conductivity, and velocity of sound. Properties are sought with significant differences that can be used for the quantitative analysis of the ortho-para composition of hydrogen at different temperatures, in particular the normal boiling point. The properties which are almost independent of ortho-para concentrations include density and viscosity. Property value differences due to ortho-para composition for density and viscosity may be expected to be of the same order of magnitude as the systematic experimental errors in their measurement.

**Table 4:** Orthohydrogen-parahydrogen equilibrium data for dihydrogen.

| Temperature, K | Mol-% para-H <sub>2</sub> |
|----------------|---------------------------|
| 10             | 99.9999                   |

Data source: [61]

The conversion from orthohydrogen to parahydrogen is exothermic. The heat of conversion in this temperature regime is 1417 J/mol (338.648 cal/mol). Liquid parahydrogen has been considered as a dump coolant to prevent boil-off of liquid oxygen in an adjacent tank during long-term in-space missions with cryogenic propellant storage for both oxidizer and fuel. The amount of heat dissipated by evaporating hydrogen can be increased (improved) by allowing conversion of parahydrogen back to orthohydrogen by passing it over a catalyst while it is warming up [63]. That conversion is an endothermic reaction and would allow more liquid oxygen to be kept at below its normal boiling point.

## 2.2 Computer Programs for Predicting Physical Properties of Hydrogen

There are a number of computer programs that give physical, thermodynamic, and transport properties of parahydrogen and equilibrium hydrogen and can be used as subroutines for modeling heat and mass flow phenomena in rocket propulsion systems [64, 65].

The pressure, temperature, and enthalpy of saturated liquid and vapor parahydrogen were presented in the form of two computer programs [66]. Using these routines and those in NBS Report 9288 “Computer programs for thermodynamic and transport properties of hydrogen” (Aug 1967), it is possible to obtain values of the saturated liquid and the saturated vapor for all of the properties given in NBS Report 9288 (density, entropy, thermal conductivity, viscosity, specific heat, and velocity of sound) [67]. Similar subroutines can be used to calculate fluid properties of normal and parahydrogen [68]. Physical properties of hydrogen and other propellants can be calculated on-line with REFPROP computer program and on-line database developed by NIST [69].

## 2.3 Physical Properties, General Information

In arranging physical properties of hydrogen in a user-friendly format, information was drawn from a multitude of sources. We are not in a position to verify the accuracy of the numbers or evaluate the reliability of one source compared to another. This results in information from multiple sources being listed in juxtaposition next to each other, usually in chronological order. This may result in some duplication of data that were referenced in one source and they in turn had drawn it from another source. Wherever possible, we have attempted to include the original, experimental source of the data.

Some surveys of information on physical properties of hydrogen are also including hydrogen isotopes [70]. Although deuterium is used as a chemical laser propellant, we have not included deuterium properties in this book. For summaries of the physical properties of hydrogen see also [41, 71–82]. Physical properties of hydrogen are summarized in Table 5.

## 2.4 Melting Point of Hydrogen

The melting point of frozen hydrogen is  $13.95\text{ K} = -259.21^\circ\text{C}$  and the triple point is at  $13.84\text{ K} = -259.32^\circ\text{C}$  at  $364\text{ kPa}$  ( $52.76\text{ Torr}$ ) [84]. Solid hydrogen as a rocket propellant would most likely be encountered in the form of hydrogen slush, a suspension of solid hydrogen in liquid hydrogen which has a higher density than liquid hydrogen. For this reason, physical properties of solid hydrogen are listed here.

For certain isotopic compositions, hydrogen may undergo a phase transition at low temperatures [70]. This transition has been studied by XRD, electron diffraction, neutron diffraction, NMR, and IR absorption. In general, all hydrogen isotopes solidify in the hexagonal close packed (hcp) structure, particularly if cooled from the liquid state. Parahydrogen appears to be stable in hcp down to the lowest temperatures in-

**Table 5:** Physical properties of hydrogen.

| Property                               | SI units                                            | Other units                                                            | References      |

vestigated. In contrast, H<sub>2</sub> rich in the ortho component (>60%) and deuterium rich in para-deuterium undergo a transition to the face centered cubic (fcc) structure in the temperature range 1.2–4.2 K. The transition temperature is a function of ortho-para concentration as well as density or pressure. The volume change of the transition is small, 1.3%, but has been measured. The melting point of parahydrogen increases with pressure, as tabulated in Table 6.

Solid hydrogen under extreme compression, about 2.8 megabars, undergoes a phase transition to the metallic state, and may be superconducting. This state may exist in the core of some of the giant gas planets like Jupiter.

**Table 6:** Melting pressures of parahydrogen as a function of temperature.

| Temperature<br>K | Pressure |       |
|------------------|----------|-------|
|                  | atm      | MPa   |

Data source: [90,91]

The melting point of  $p\text{-H}_2$  was measured at high pressures up to 35.46 MPa (350 atm) [92, 93]. The melting curve of solid parahydrogen in Figure 4 can be expressed by the equation

$$(P - P_t)/(T - T_t) = \left[ A \exp\left(\frac{-\alpha}{T}\right) + BT \right]$$

where  $P_t$  is the triple point pressure 0.00704 MPa,  $T_t$  is the triple point temperature 13.803 K,  $A = 30.3312 \text{ atm/K}$ ,  $\alpha = 5.693 \text{ K}$ ,  $B = 2/3 \text{ atm/K}^2$  [41].

Figure 4: Melting line for parahydrogen at 0.6 to 200 MPa. (Reproduced and modified from [41].)

## 2.5 Boiling Point of Hydrogen

The boiling point of normal hydrogen is at  $20.38\text{ K} = -252.78^\circ\text{C}$  [85] and the boiling point of parahydrogen is at  $20.27\text{ K} = -252.89^\circ\text{C}$  [61].

## 2.6 Density and Molar Volumes of Hydrogen

### 2.6.1 Density of Gaseous Hydrogen

The real gas behavior of normal hydrogen gas at pressures up to 101 MPa was measured in order to create a PVT diagram covering a wide range of pressures and temperatures [94]. The PVT and thermophysical properties of compressed normal hydrogen (75% orthohydrogen and 25% parahydrogen) up to 100 MPa and its equation of state derived from the measurement data of the Burnett method, along with the measurement methods and correlation of viscosity and thermal conductivity for compressed hydrogen were summarized in [95].

### 2.6.2 Density of Condensed Phase Hydrogen

Density data for solid and liquid hydrogen under atmospheric ambient pressure are listed in Table 7.

**Table 7:** Density of solid and liquid hydrogen.

| State                                                  | Temperature, K              | Density $\rho^a$ , g/cm <sup>3</sup> | References |
|--------------------------------------------------------|-----------------------------|--------------------------------------|------------|

|                                                        | 26.00                       | 0.06282                              |            |
|                                                        | 28.00                       | 0.05896                              |            |
|                                                        | 30.00                       | 0.05392                              |            |
|                                                        | 32.00                       | 0.04595                              |            |
| Critical                                               | 32.984 = $T_{\text{crit.}}$ | 0.03078 = $\rho_{\text{crit.}}$      |            |

Note: <sup>a</sup> Experimental values, except <sup>b</sup> which is calculated

If the critical density is known, the density of liquid parahydrogen from the melting point up to 31 K can be calculated from the following equation [86]:

$$\rho - \rho_{\text{crit.}} = 2.016 \left[ -0.001810 + 0.0092597 (T_{\text{crit.}} - T)^{\frac{1}{3}} \right]$$

where  $\rho_{\text{crit.}}$  is the critical density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin. The original equation was in gram-mols/cm<sup>3</sup> and in order to convert to g/cm<sup>3</sup> we had to multiply it by 2.016, the molecular mass of dihydrogen. As shown in Figure 5, the density of parahydrogen is slightly less than that of normal hydrogen.

**Figure 5:** Calculated density of saturated liquid parahydrogen and normal hydrogen. (Chart created by Schmidt 2016 based on data from [86].)

The density of subcooled liquid hydrogen is strongly dependent of the temperature and only slightly dependent of the pressure. A simplified state equation for this region was given as [97]

$$\ln \rho = b_0 + b_1 T^{\frac{9}{4}}$$

$$b_0 = -2.532955 + 3.588795 \times 10^{-2} P$$

$$b_1 = -1.694709 + 2.248987 \times 10^{-5} P$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$ ,  $T$  is the temperature in K, and  $P$  is the pressure in MPa.

The density of condensed-phase hydrogen was measured from 15 to 100 K at pressures up to 350 atmospheres [92, 93]. The accuracy of these measurements ( $\pm 0.03\%$ ) was insufficient to detect any difference between the densities of liquid normal and parahydrogen.

In a representation of pressure-density-temperature relations of fluid parahydrogen from 15 to 100 K at pressures to 350 atmospheres, the range of experimental densities was from 0.064 to 2.8 times the critical density [98]. This publication contains lots of numbers but no graphs.

The molar volume of liquid  $p\text{-H}_2$  at the triple point is  $26.17 \text{ cm}^3/\text{mol}$ . Subtracting  $\Delta V$ , one obtains  $23.30 \text{ cm}^3/\text{mol}$  for the molar volume of solid  $p\text{-H}_2$  at the triple point. Density data for liquid and gaseous hydrogen from multiple sources were correlated in [99].

Two different curve-fit equations were given for the specific volume of solid  $p$ -H<sub>2</sub> as a function of temperature, a simple linear equation and a polynomial equation [100]:

$$V_s = 27.1788 - 0.283044 T$$

$$V_s = 23.4469 + 0.376708 T - 0.0380559 T^2 + 0.000715738 T^3$$

where  $V_s$  is the molar volume in cm<sup>3</sup>/mol and  $T$  is the temperature in kelvin. The cubic polynomial equation is not much more accurate than the linear equation. Using the best data available, a PVT diagram for  $p$ -H<sub>2</sub> was constructed (Figure 6). On this diagram the molar volume (cm<sup>3</sup>/mol) of solid  $p$ -H<sub>2</sub> has been plotted vs. temperature in a series of isobars ranging from 0 to 400 atm pressure. Above the melting line on Figure 6 they have plotted the freezing line for the liquid and a few of the isobars for liquid  $p$ -H<sub>2</sub>. The lower part of this graph is similar to Figure 40a on page 5–43 of [41], shown here as Figure 7, except that the more recent graph contains data all the way up to 800 atm instead of only 400 atm.

**Figure 6:** PVT Diagram for liquid and solid parahydrogen. (Reproduced and modified from [100].)

**Figure 7:** PVT diagram for compressed solid parahydrogen. (Reproduced and modified from [41].)

The most striking anomaly about the PVT diagram in Figure 6 is the shape of the isobars near the melting line. It is seen that at pressures above 150 atm there is a narrow temperature region in which the molar volume of solid  $p$ -H<sub>2</sub> increases as the temperature is lowered at constant pressure, instead of decreasing, as one would expect. The density of parahydrogen in a  $P$ – $\rho$ – $T$  diagram is illustrated in Figure 8.

The density of liquid hydrogen as a function of temperature can be displayed graphically or printed out as a table by an on-line app on the NIST Chemistry Web-Book Fluids web page [101]. A sample calculation for saturated hydrogen  $14 < T < 33$  K is shown in Figure 9.

### 2.6.3 Density near the Critical Point

Closely spaced experimental data were used for defining a consistent set of values for critical constants that describe the two-phase boundaries between saturated liquid and saturated vapor [102]. The PVT properties of 20.3 K equilibrium hydrogen (0.21% orthohydrogen), herein simply called parahydrogen, were measured by Goodwin et al. [98]. The experimental runs were conducted at nearly constant

**Figure 8:**  $P$ – $\rho$ – $T$  density diagram of parahydrogen. (Reproduced and modified from [41].)

**Figure 9:** Density of liquid and gaseous hydrogen along the saturation line. (From [101].)

density (pseudo-isochores) by taking pressure measurements at numerous fixed temperatures. The density near the critical point can be expressed by the equation

$$\rho = \rho_c + A(T_c - T)^{0.370} + B(T_c - T) + C(T_c - T)^{0.7} + D(T_c - T)^{0.8}$$

where  $\rho$  is the density in mol/cm<sup>3</sup>,  $\rho_c$  is the critical density  $\rho_c = 0.01559 \pm 0.00005$  mol/cm<sup>3</sup>,  $T$  is the temperature in kelvin,  $T_c$  is the critical temperature  $T_c = 32.976 \pm 0.015$  K and  $A$ ,  $B$ ,  $C$  and  $D$  are constants ( $A = -0.71967724 \times 10^{-2}$ ,  $B = 0.14495527 \times 10^{-2}$ ,  $C = 0.32403120 \times 10^{-2}$ ,  $D = -0.44640177 \times 10^{-2}$ ). The experimental

configuration used yielded a flatter dome, shown in Figure 10 as the dashed line. The solid line represents the computed results, and circles represent the experimental values.

#### 2.6.4 Density of Solid Hydrogen

The molar volume ( $V_s$ ) of solid parahydrogen along the melting line up to a temperature of about 24 K and a pressure of about 400 atm has been determined by two independent methods: direct measurement and computation from the heat of fusion and change in volume during melting [103]. Results obtained by the two methods agreed with each other within about  $\pm 0.2\%$ ; they were both referred to as “experimental.” The empirical linear equation

$$V_s = 27.1788 - 0.283044 T$$

where  $V_s$  is the molar volume in  $\text{cm}^3/\text{mol}$  and  $T$  is the temperature in kelvin, reproduced the experimental results with a mean deviation of about 0.15%. The molar volume of solid hydrogen at the triple point is  $22.561 \text{ cm}^3/\text{mol}$ .

The density of melting solid hydrogen as a function of the melting temperature under pressure along the melting line can be calculated from a curve-fitted linear equation [90]

$$\rho = 0.06924 + 0.00123T$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin. Note that the melting temperature increases with pressure, and thus the density increases with temperature and pressure along the melting line. Density data along with dielectric constants of solid hydrogen under pressure are shown in Table 38.

## 2.7 Compressibility of Hydrogen

### 2.7.1 Compressibility of Liquid Hydrogen

The isothermal compressibility is defined as

$$\beta_T = \frac{1}{V} \left( \frac{\partial V}{\partial T} \right)_T$$

The isothermal compressibility is a negative quantity. The isothermal compressibility of liquid hydrogen is  $-1.10 \times 10^{-2} \text{MPa}^{-1}$  at the triple point and  $-1.99 \times 10^{-2} \text{MPa}^{-1}$  at the boiling point.

The adiabatic (isentropic) compressibility is defined as

$$\beta_S = \frac{1}{V} \left( \frac{\partial V}{\partial T} \right)_S = \frac{C_V}{C_P} \beta_T$$

The adiabatic compressibility of liquid parahydrogen is  $0.00807 \text{MPa}^{-1}$  at the triple point and  $0.0119 \text{MPa}^{-1}$  at the boiling point. The adiabatic compressibility of gaseous parahydrogen is  $8.56 \text{MPa}^{-1}$  at the triple point and  $5.93 \text{MPa}^{-1}$  at the boiling point. Adiabatic compressibility and sonic velocity are closely related by the relationship

$$\beta_S = \frac{1}{\rho c^2}$$

where  $\rho$  is the density and  $c$  is the velocity of sound. Density, coefficient of thermal expansion, velocity of sound, and compressibility data of liquid parahydrogen at sea level pressure are summarized in Table 8.

Measured isotherms of liquid normal hydrogen from the boiling point to the critical point were tabulated for seven temperature intervals between 20.38 and 32.58 K at pressures up to 100 atm [105]. The compressibility can be derived from these data by plotting the isochors, which gives straight lines which can be expressed by a linear equation (Table 9).

**Table 8:** Density, velocity of sound, compressibility, and coefficient of thermal expansion of liquid parahydrogen.

| Temperature<br>K | Density<br>g/cm <sup>3</sup> | Velocity of<br>sound<br>m/s | Adiabatic<br>compressibility |                                         | Isothermal<br>compressibility |                                         | Coefficient<br>of thermal<br>expansion<br>1/K |

Based on specific volume PVT data from [105]

The compressibility coefficient is defined as

$$C = \frac{P}{V} \left( \frac{\partial V}{\partial P} \right)_T$$

This quantity may be easily obtained by forming the product of  $P$  times the isothermal compressibility. The compressibility coefficient of liquid hydrogen is  $7.79 \times 10^{-5}$  at the triple point and  $2.02 \times 10^{-3}$  at the boiling point. The compressibility factor is defined as  $Z = PV/RT$ . The compressibility factor of liquid hydrogen is 0.00161 at the triple point, 0.01712 at the boiling point and 0.3024 at the critical point.

The isothermal compressibility of liquid hydrogen has been listed as  $-1.10 \times 10^{-2} \text{ MPa}^{-1} = -1.10 \times 10^{-8} \text{ Pa}^{-1}$  at the triple point and  $-1.99 \times 10^{-2} \text{ MPa}^{-1} = -1.99 \times 10^{-8} \text{ Pa}^{-1}$  at the boiling point [79].

The compressibility of liquid and solid hydrogen has been measured up to very high pressures, trying to find the transition point to metallic hydrogen. Conditions like this may exist in the interior of the gaseous giant planets but are not likely to be encountered in rockets.

High explosives were used to shock liquid hydrogen to 39500 bar pressure, compress it to a specific volume of  $5.2 \text{ cm}^3/\text{g}$  and an estimated temperature of 1100 K from an initial state near the normal boiling point, 20.5 K and  $14.1 \text{ cm}^3/\text{g}$  [106]. The derived intermolecular potential between two hydrogen molecules was shown to be inadequately represented by the previously postulated Lennard-Jones 6–12 potential in the repulsive region between 2.0 and 2.7 Å. The power of the inverse intermolecular distance is shown instead to be 8.5 in that region if a purely repulsive potential is used. These experiments predated the discovery of metallic hydrogen. Liquid hydrogen was isentropically compressed to a density of  $1 \text{ cm}^3/\text{g}$  at 2 MPa by a combination of magnetic field constriction and explosive implosion [106].

### 2.7.2 Compressibility of Gaseous Hydrogen

Compressibility isotherms of hydrogen were given at temperatures from 98 to 298 K (–175 to 25 °C) and at maximum pressure of 1000 atm, also at temperatures from 273 to 423 K (0–150 °C) and at maximum pressure of 2950 atm [107]. Values of the second and third virial coefficients of hydrogen were calculated from experimental PVT data with the method of least squares in the temperature range from 423 to 98 K (150 to –175 °C) [108]. Theoretical values of the second virial coefficient were calculated in the same temperature range, based on the Lennard-Jones potential field and on parameter values taken from the literature, with corrections for the non-spherical part of the potential and for a number of quantum effects. A comparison showed that a satisfactory representation of the experimental data with a Lennard-Jones potential was impossible, even after adjustment of the parameter values to the experimental results.

### 2.7.3 Compressibility of Solid Hydrogen

The isothermal compressibility of solid parahydrogen was measured in the temperature range of 6–14.5 K and at pressures of 0–180 atm on the basis of dielectric constant measurements [109].

## 2.8 Velocity of Sound in Liquid Hydrogen

The velocity of sound in liquid parahydrogen is 1264 m/s at the triple point and 1089 m/s at the normal boiling point. The velocity of sound in gaseous parahydrogen is 305.7 m/s at the triple point and 355 m/s at the normal boiling point. Figure 11 illustrates the velocity of sound in parahydrogen for a wide range of temperatures and pressures [41]. The unit of pressure on the auxiliary parameter curves is psia. Data for normal hydrogen are available from the same source but they are not much different.

**Figure 11:** Velocity of sound in parahydrogen. (Reproduced and modified from [41].)

Liquid hydrogen has been compressed in shock waves from explosive charges in an attempt to create metallic hydrogen [110]. High explosives were used to shock liquid hydrogen to 39500 bar,  $5.2 \text{ cm}^3/\text{g}$  and an estimated temperature of 1100 K from an initial state near the normal boiling point, 20.5 K and  $14.1 \text{ cm}^3/\text{g}$ . It was attempted to calculate the repulsive potential between two hydrogen molecules and two hydrogen atoms as they are squeezed together at high pressures. Hydrogen isotopes are subjected to very high pressures when they are packaged in targets for controlled nuclear fusion experiments.

Based on measured values of  $P$  vs.  $V$ , isotherms of normal liquid hydrogen were tabulated for 7 temperatures between 20.38 and 32.58 K [105]. Then the data were re-plotted as isochores, and a straight line relationship could be adequately described by

$$P = A_v + B_v T$$

$$B_v = -7.11 + 437 \left( \frac{1}{V} \right)$$

The velocity of ultrasonic waves in liquid hydrogen depends upon the orthohydrogen-parahydrogen concentration in the liquid. Between 14 and 20 K the velocity in a 99.8% parahydrogen mixture is about 8 m/s or about 0.6% smaller than in the non-equilibrated 25% mixture [111]. No influence of frequency on velocity of sound could be detected in the frequency range from 1 to 5 MHz. The adiabatic compressibility of the equilibrium mixture exceeds that of the normal hydrogen by about 2%.

It had been shown that the velocity of sound in liquid hydrogen is dependent on the orthohydrogen-parahydrogen concentration at temperatures between 13 and 20 K. These measurements were later extended to near the critical point [112].

The specific heat  $C_p$ , the thermal expansion coefficient  $\alpha$  and the pressure coefficient  $\gamma_p$  are well known for liquid normal or parahydrogen in equilibrium with saturated vapor. Combining these data with experimental values of the velocity of sound, one is able to calculate other thermodynamic properties, e.g. the specific heats  $C_p$  and  $C_v$ , the compressibility coefficients  $\beta_S$  and  $\beta_T$ , the expansion coefficient  $\alpha$ , the pressure coefficient  $\gamma_p$ , and the derivative  $dp/dt$  [113].

The most comprehensive measurements of the velocity of sound in liquid hydrogen have been made by Younglove, Figure 12 [114]. The measurements cover temperatures from 15 to 100 K and pressures up to 300 atm. Calculations based on previous pressure density and temperature measurements of this laboratory provide the density corresponding to each experimental temperature and pressure. Prior to this work no known experimental velocities had been determined for compressed liquid parahydrogen above 21 K.

Figure 13 is taken from a later reference to illustrate the slight difference in velocity of sound between saturated liquid normal and parahydrogen. The two lines nearly fall on top of each other.

The difference in the velocity of sound between that of liquid normal and that of parahydrogen is emphasized in Figure 14. The difference increases with temperature past the normal boiling point of hydrogen.

The velocity of sound in highly compressed hydrogen was measured from Brillouin scattering in a diamond anvil cell at 1.2–5.0 GPa at 293 K and also at 4.6–13 GPa over a wider temperature range 300–530 K [115]. From these velocity of sound data together with previously reported volume and ultrasonic velocity data at low pressures

**Figure 12:** Velocity of sound as a function of density, showing isotherms. (Reprinted and modified from [114], with permission from ©1965 Acoustic Society of America; permission conveyed through RightsLink.)

Legend: The dashed lines are calculated values. The heavy lines are phase boundaries. For reference, the densities of the critical point and triple point are indicated on the abscissa.

and temperatures, a Benedict type PVT equation of state was derived that is valid for fluid hydrogen up to the maximum pressures and temperatures with an average deviation of 1% from the new and previously published experimental data.

## 2.9 Vapor Pressure of Hydrogen

Table 10 is a summary of vapor pressure data for normal (75% *o*-H<sub>2</sub>, 25% *p*-H<sub>2</sub>) liquid hydrogen calculated using equation

$$\log_{10} p = 4.66687 - 44.9569/T + 0.020537T$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

**Figure 13:** Velocity of sound in liquid parahydrogen and normal hydrogen. (Reproduced and modified from [70].)  
Legend: The open circles are for normal hydrogen.

**Figure 14:** Difference in velocity of sound between liquid normal and parahydrogen. (Reproduced and modified from [62]; based on data from Younglove 1965.)

**Table 10:** Calculated vapor pressure of normal liquid hydrogen.

| Temperature |         | Vapor Pressure |        |
|-------------|---------|----------------|--------|
| K           | °C      | kPa            | atm    |
| 14.00       | −259.16 | 7.38           | 0.0728 |
| 16.00       | −257.16 | 20.4           | 0.2018 |
| 18.00       | −255.16 | 46.1           | 0.4551 |
| 20.00       | −253.16 | 90.1           | 0.8891 |
| 22.00       | −251.16 | 158            | 1.564  |
| 24.00       | −249.16 | 258            | 2.545  |
| 26.00       | −247.16 | 395            | 3.899  |
| 28.00       | −245.16 | 577            | 5.695  |
| 30.00       | −243.16 | 812            | 8.010  |
| 32.00       | −241.16 | 1103           | 10.923 |
| 33.00       | −240.16 | 1280           | 12.632 |

Data source: [61]

A similar equation exists for solid normal hydrogen

$$\log_{10}p = 4.56488 - 47.2059/T + 0.03939T$$

where  $p$  is the vapor pressure in mmHg and  $T$  is the temperature in Kelvin. Corresponding equations for the equilibrium composition at 20.4 K which is mostly parahydrogen (actually, 99.79%  $p$ -H<sub>2</sub> and 0.21%  $o$ -H<sub>2</sub>) are for the liquid

$$\log_{10}p = 4.64392 - 44.3450/T + 0.02093T$$

and for the solid:

$$\log_{10}p = 4.62438 - 47.0172/T + 0.03635T$$

where  $p$  is the vapor pressure in mmHg and  $T$  is the temperature in Kelvin. Corresponding equations for normal hydrogen consisting of 75% orthohydrogen and 25% parahydrogen are for the liquid:

$$\log_{10}p = 4.66687 - 44.9569/T + 0.020537T$$

and for the solid:

$$\log_{10}p = 4.56488 - 47.2059/T + 0.03939T$$

Measured vapor pressure data for normal liquid hydrogen are presented in Table 11.

**Table 11:** Vapor pressure of normal liquid hydrogen, measured data.

| Temperature |         | Vapor pressure |         |
|-------------|---------|----------------|---------|
| K           | °C      | kPa            | atm     |
| 20.90       | −252.26 | 117.5          | 1.1596  |
| 22.65       | −250.51 | 184            | 1.8155  |
| 23.72       | −249.44 | 238            | 2.3493  |
| 24.73       | −248.43 | 299            | 2.9510  |
| 25.70       | −247.46 | 366            | 3.6126  |
| 26.74       | −246.42 | 448            | 4.4178  |
| 28.20       | −244.96 | 584            | 5.7618  |
| 30.19       | −242.97 | 817            | 8.0645  |
| 31.40       | −241.76 | 983            | 9.6981  |
| 32.36       | −240.80 | 1135           | 11.2065 |
| 33.14       | −240.02 | 1279           | 12.620  |
| 33.24       | −239.92 | 1297           | 12.797  |

Data source: [116]

These values can be represented by the following polynomial equation:

$$\log p_v = 3.068281 - 55.25642/T - 3.1282 \times 10^{-2} T + 6.6989 \times 10^{-4} T^2$$

where  $T$  is the temperature in kelvin and  $p_v$  is the vapor pressure in atm.

**Table 12:** Comparison of measured and interpolated vapor pressures of parahydrogen.

| Temperature, K | Vapor pressure, atm, measured | Vapor pressure, atm, calculated |
|----------------|-------------------------------|---------------------------------|
| 20.268         | 1.0000                        | 0.9999                          |

Data source: [117]

Table 12 is a comparison of measured and interpolated vapor pressures of parahydrogen (frozen equilibrium concentration at 20 K) by using the following equation [117]

$$\log p_v = 2.000620 - 50.09708/(T + 1.0044) + 1.748495 \times 10^{-2} T$$

where  $T$  is the temperature in kelvin and  $p_v$  is the pressure in atm. Vapor pressure and density of normal saturated liquid hydrogen are listed in Table 13.

The vapor pressure data for normal hydrogen from [118] in the range from 21.01 to 32.27 K can be expressed by the Antoine equation

$$\log p = 3.54314 - [99.395/(T + 7.726)]$$

where  $p$  is the pressure in bar and  $T$  is the temperature in kelvin.

**Table 13:** Saturation properties, normal hydrogen, liquid-vapor.

| Temperature | Pressure | Vapor pressure<br>slope $dP/dT$ | Density, sat.<br>liquid | Density, sat.<br>vapor |
|-------------|----------|---------------------------------|-------------------------|------------------------|

Data source: [70], p. 13

The NBS values for the vapor pressure of liquid  $p\text{-H}_2$  in the temperature range below the normal boiling point from 13.803 to 20.268 K are given by the simple equation [74]:

$$\log P = a + \frac{b}{T} + cT$$

where  $a = 1.772454$ ,  $b = -44.36888$ , and  $c = +0.02055468$  are constants,  $P$  is the pressure in atm, and  $T$  is the temperature in kelvin. Above the normal boiling point from 20.26 to 29.00 K a slightly different equation can be used:

$$\log P = A + B/(T + C) + DT$$

where  $A = +2.000620$ ,  $B = -50.09708$ ,  $C = +1.0044$ ,  $D = +0.01748495$  are constants,  $P$  is the pressure in atm, and  $T$  is the temperature in kelvin. These two equations reproduce experimental vapor pressures within 0.002 atm and are accurate enough for daily use.

**Figure 15:** Vapor pressure of parahydrogen below 0.101 MPa. (Reproduced and modified from [41].)

The vapor pressure of parahydrogen can be calculated from the very complex equation from [119]:

$$\ln\left(\frac{P}{P_t}\right) = n_1x + n_2x^2 + n_3x^3 + n_4(1-x)^{n_5}$$

where  $n_1 = 3.05300134164$ ,  $n_2 = 2.80810925813$ ,  $n_3 = -0.655461216567$ ,  $n_4 = 1.59514439374$ ,  $n_5 = 1.5814454428$ ,  $x = (1 - T_t/T)/(1 - T_t/T_c)$ , with  $T_t = 13.8$  K,  $T_c = 32.938$  K, and  $P_t = 0.007042$  MPa.

Vapor pressure of liquid parahydrogen as a function of temperature for temperatures below the normal boiling point is illustrated in Figure 15 and data for temperatures above the normal boiling point are illustrated in Figure 16. For additional (sometimes antiquated) vapor pressure data see also [120].

Vapor pressure data in the literature often lack information as to the temperature scale being used for calibration of thermometers. Other authors fail to correct for other deviations expected from pressure measurements. It would be difficult to decide if the *o-p* composition of liquid hydrogen has an effect on the vapor pressure. Such measurements would have to be made side by side with exactly the same equipment.

**Figure 16:** Vapor pressure of parahydrogen above 0.101 MPa. (Reproduced and modified from [41].)

Van Itterbeek, et al. [118] measured the difference in vapor pressure of normal and parahydrogen and the vapor pressure of normal hydrogen, simultaneously. The normal boiling points of normal and parahydrogen were determined to be 20.389 and 20.269 K, respectively. The vapor pressure results were reported as accurate to within  $\pm 0.004$  atm. The vapor pressure differences of the Wooley et al. 1948 and Itterbeek et al. 1964 measurements are illustrated in Figure 17 and seem to match each other in the range where they overlap. There is a substantial difference between the vapor pressures of normal and parahydrogen. The difference increases with increasing temperatures.

**Figure 17:** Vapor pressure difference between liquid normal and parahydrogen. (Reproduced and modified from [62].)

The sublimation vapor pressure of solid hydrogen below the triple point is very low, but it can still sublime. The vapor pressure of solid parahydrogen is somewhat higher than that of normal hydrogen (Figure 18). The line for parahydrogen in Figure 18 for temperatures below 10 K can be represented by the equation (based on data from [121]):

$$\log P = 43.39/T + 2.5 \log T + 2.047$$

The sublimation pressure of solid parahydrogen can be expressed by a Kirchoff-Rankine equation:

$$\log P = \frac{A}{T} + B \log T + C$$

where  $P$  is the sublimation pressure in mmHg,  $T$  is the temperature in kelvin, and  $A$ ,  $B$ , and  $C$  are constants, with  $A = -90.77568949$ ,  $B = 2.489830940$ , and  $C =$

**Figure 18:** Vapor pressure of solid hydrogen. (Reproduced and modified from [41].)

4.009857354 [122]. This equation has been forced to go through the triple point at  $P_t = 0.00704$  MPa (0.0695 atm) and,  $T_t = 13.80$  K. See also [123].

## 2.10 Viscosity of Hydrogen

The viscosity differences of gaseous orthohydrogen and parahydrogen are small, approaching 1% near the triple point [124, 125]. In all cases the para modification had the slightly higher viscosity. Liquid hydrogen viscosity values, however, differ by larger amounts with differences of about 5% at saturation near the triple point.

2.10.1 Viscosity of Liquid Hydrogen

The viscosity of normal liquid hydrogen was measured by observing its flow through a variety of capillary tubes and the data are listed in Table 14. The resulting viscosities were about 10% higher than those obtained by [126] using an oscillating disc. Figure 19 compares liquid hydrogen viscosity data from three different sources [127].

**Figure 19:** Viscosity of liquid hydrogen. (Reprinted and modified from [127], with permission from ©1962 Elsevier; permission conveyed through RightsLink.)

Table 15 lists the density and viscosity of liquid parahydrogen as a function of temperature. The measurable difference in viscosity of saturated liquid normal and parahydrogen is illustrated in Figure 20.

**Table 14:** Viscosity of normal liquid hydrogen.

| Temperature |        | Viscosity |         |
|-------------|--------|-----------|---------|
| K           | °C     | mPa s     | cPs     |

Data source: [129]

Figure 20: Viscosity difference between saturated liquid normal hydrogen and parahydrogen. (Reproduced and modified from [62]; based on data from Diller 1965.)

The viscosity of liquid hydrogen as a function of temperature can be displayed graphically or printed out as a table by an on-line app on the NIST Chemistry Web-Book Fluids web page [101]. A sample calculation for saturated hydrogen  $14 < T < 33$  K is shown in Figure 21.

The viscosity of liquid parahydrogen at just above the triple point is  $255.1 \times 10^{-7} \text{ kg m}^{-1} \text{ s}^{-1}$  and at a temperature just below the boiling point it is  $132.0 \times 10^{-7} \text{ kg m}^{-1} \text{ s}^{-1}$ . The viscosity of liquid hydrogen at the critical point is  $35.43 \times 10^{-7} \text{ kg m}^{-1} \text{ s}^{-1}$ .

A piezoelectric alpha quartz torsional oscillator technique was used to measure liquid hydrogen viscosity. There is only a minimal difference in the viscosity of liquid parahydrogen and non-equilibrium normal hydrogen at temperatures between 10 and 14 K [130].

**Figure 21:** Viscosity of liquid and gaseous hydrogen along the saturation line. (From NIST RefProp [101].)

The viscosity at 14 K of a liquid containing 68% orthohydrogen was 4% higher than that of a liquid containing only 28% orthohydrogen. Theoretical calculations predicted higher viscosity for gaseous orthohydrogen-rich equilibrium mixtures than for parahydrogen non-equilibrium gas, and the similar trend may be true for the liquid.

Fundamental transport properties of liquid parahydrogen ( $p\text{-H}_2$ ) including shear viscosity and bulk viscosity, have been evaluated over a wide temperature range, 14–32 K, by means of path integral centroid molecular dynamics (CMD) calculations [131]. For the bulk viscosity of liquid  $p\text{-H}_2$ , which was never known from experiments, the present CMD has given a clear temperature dependence. In addition, from the comparison based on the principle of corresponding states, it has been shown that the marked deviation of the transport properties of liquid  $p\text{-H}_2$  from the properties expected from the molecular parameters is due to the quantum effect.

A survey of experimental data for the viscosity of hydrogen, which is needed for many applications in system analysis and design, included an analysis of the current standard models for thermal conductivity and viscosity of normal hydrogen and parahydrogen, which are based on measurement and correlation work done before the mid-1980s, and collected more than 100 literature references on transport properties of hydrogen and a few on transport properties of parahydrogen [132]. Properties calculated with these models were analyzed and compared to all available experimental data for normal hydrogen and parahydrogen, and percent deviations of individual data sets from the computed mean were graphed.

A wide-ranging correlation for the viscosity of normal hydrogen covering the temperature range from the triple-point temperature to 1000 K and pressures up to 200 MPa was derived from literature data [133]. It can extrapolate to 2000 K with an estimated uncertainty of 4% for the saturated liquid from the triple point to 31 K, with larger deviations as the critical region is approached. The estimated uncertainty is 4% for the supercritical fluid phase at pressures to 200 MPa. For the limited range of 200–400 K at pressures up to 0.1 MPa, the uncertainty is 0.1%.

2.10.2 Viscosity of Gaseous Hydrogen

Table 16 lists viscosity data for gaseous hydrogen at atmospheric pressure.

Table 16: Viscosity of normal gaseous hydrogen.

| Temperature, K | Viscosity                       |                         |
|----------------|---------------------------------|-------------------------|
|                | $\text{N s}^{-1} \text{m}^{-2}$ | $\text{Ps} \times 10^7$ |
| 10             | $5.10 \times 10^{-7}$           | 51.0                    |
| 20             | $1.093 \times 10^{-6}$          | 109.3                   |
| 30             | $1.607 \times 10^{-6}$          | 160.7                   |
| 40             | $2.068 \times 10^{-6}$          | 206.8                   |
| 50             | $2.489 \times 10^{-6}$          | 248.9                   |
| 60             | $2.876 \times 10^{-6}$          | 287.6                   |
| 70             | $3.238 \times 10^{-6}$          | 323.8                   |
| 80             | $3.579 \times 10^{-6}$          | 357.9                   |
| 90             | $3.903 \times 10^{-6}$          | 390.3                   |
| 100            | $4.211 \times 10^{-6}$          | 421.1                   |
| 110            | $4.508 \times 10^{-6}$          | 450.8                   |
| 120            | $4.793 \times 10^{-6}$          | 479.3                   |
| 130            | $5.070 \times 10^{-6}$          | 507.0                   |
| 140            | $5.338 \times 10^{-6}$          | 533.8                   |
| 150            | $5.598 \times 10^{-6}$          | 559.8                   |
| 160            | $5.852 \times 10^{-6}$          | 585.2                   |
| 170            | $6.100 \times 10^{-6}$          | 610.0                   |
| 180            | $6.343 \times 10^{-6}$          | 634.3                   |
| 190            | $6.581 \times 10^{-6}$          | 658.1                   |
| 200            | $6.814 \times 10^{-6}$          | 681.4                   |
| 210            | $7.043 \times 10^{-6}$          | 704.3                   |
| 220            | $7.269 \times 10^{-6}$          | 726.9                   |
| 230            | $7.490 \times 10^{-6}$          | 749.0                   |
| 240            | $7.709 \times 10^{-6}$          | 770.9                   |
| 250            | $7.924 \times 10^{-6}$          | 792.4                   |
| 260            | $8.136 \times 10^{-6}$          | 813.6                   |
| 270            | $8.346 \times 10^{-6}$          | 834.6                   |
| 280            | $8.553 \times 10^{-6}$          | 855.3                   |
| 290            | $8.758 \times 10^{-6}$          | 875.8                   |
| 300            | $8.960 \times 10^{-6}$          | 896.0                   |
| 310            | $9.160 \times 10^{-6}$          | 916.0                   |
| 320            | $9.358 \times 10^{-6}$          | 935.8                   |
| 330            | $9.554 \times 10^{-6}$          | 955.4                   |
| 340            | $9.748 \times 10^{-6}$          | 974.8                   |
| 350            | $9.940 \times 10^{-6}$          | 994.0                   |
| 360            | $1.013 \times 10^{-5}$          | 1013                    |

Table 16: (continued)

| Temperature, K | Viscosity                      |                         |
|----------------|--------------------------------|-------------------------|
|                | $\text{Ns}^{-1} \text{m}^{-2}$ | $\text{Ps} \times 10^7$ |

| 1020           | $2.040 \times 10^{-5}$         | 2040                    |
| 1040           | $2.066 \times 10^{-5}$         | 2066                    |
| 1060           | $2.092 \times 10^{-5}$         | 2092                    |
| 1080           | $2.118 \times 10^{-5}$         | 2118                    |
| 1100           | $2.144 \times 10^{-5}$         | 2144                    |

The viscosity of gaseous  $n\text{-H}_2$  at atmospheric pressure in the range from 13.97 to 1280 K can be represented by the following polynomial equation [134, 135].

$$\eta = 2.105 + 0.4774 T - 9.9784 \times 10^{-4} T^2 + 1.61827 \times 10^{-6} T^3 \\ - 1.28024 \times 10^{-9} T^4 + 3.8164 \times 10^{-13} T^5$$

where  $\eta$  is the viscosity in micro Poise and  $T$  is the temperature in kelvin. The orthohydrogen-parahydrogen composition of gaseous hydrogen has no influence on the viscosity.

Plotting the logarithm of the viscosity of hydrogen versus the logarithm of the reduced temperature  $T/T_c$  gives almost a straight line, extending both below and above the critical point, expressed by the equation for temperatures up to 100 K

$$\mu_p^* = 1.004 \mu_n^{1.0019}$$

where  $\mu_p^*$  is the viscosity of gaseous parahydrogen at 1 atm and  $\mu_n$  is the viscosity of gaseous normal hydrogen at 1 atm, as shown in Figure 22, from [136]. The critical temperature used for these calculations was 32.976 K.

**Figure 22:** Viscosity of gaseous parahydrogen at atmospheric pressure and cryogenic temperatures. (Republished and modified from [136], with permission of ©1967 American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center Inc.)

Viscosity and density data of gaseous normal hydrogen at high pressures are listed in Table 17.

**Table 17:** Viscosity and density of gaseous normal hydrogen at high pressures.

| Temperature |     | Pressure |       | Density           | Viscosity              |               |
|-------------|-----|----------|-------|-------------------|------------------------|---------------|

Data source: [137], which contains data for pressures up to 200 atm

Experimental values for the viscosity of hydrogen at atmospheric pressure were gathered from the literature and plotted against the reduced temperature. A viscosity correlation for hydrogen has been developed for reduced temperatures up to  $T_R = 75$  (at which point dissociation becomes noticeable) and reduced pressures up to  $P_R = 100$ , see [138]. Experimental viscosities available in the literature for hydrogen at moderate pressures were used to establish the atmospheric pressure viscosity behavior of hydrogen. For each experimental high-density value, the residual viscosity,  $\mu - \mu^*$ , was determined from the atmospheric pressure relationship and plotted against reduced density to produce a continuous curve for both the gaseous and liquid regions. This information enabled a plot of viscosity against reduced temperature and reduced pressure to be developed for hydrogen. No significant difference exists between the viscosities of orthohydrogen and parahydrogen. Viscosity values of dissociating hydrogen for temperatures up to 5000 K were obtained from reported theoretical calculations and were plotted against temperature for constant pressures.

Measurements of the viscosity and thermal conductivity of gaseous parahydrogen and normal hydrogen from 15 to 5000 K, including the dissociation region, were critically evaluated and correlated by means of a dilute gas kinetic theory [139].

Figure 23 shows the viscosity of liquid and gaseous hydrogen over a wide range of temperatures and pressures. At the coarse scale of this graph, there is no noticeable difference in the viscosity of parahydrogen or normal hydrogen.

**Figure 23:** Dynamic viscosity of liquid and gaseous hydrogen at high pressures. (Reproduced and modified from [41].)

Using appropriate force constants and a collision integral for the Chapman-Enskog solution the viscosity of hydrogen gas can be estimated [140]. At high density, modification of Diller's extrapolation equation for excess viscosity gave good agreement with the available experimental data. A combination of the Chapman-Enskog solution and modification of Diller's excess viscosity gave estimated hydrogen gas viscosity within 2–4% deviation from the existing experimental data for the high-temperature and high-pressure region.

A capillary tube viscometer was used to measure the dynamic viscosity of hydrogen under high pressures and at high temperatures [141]. A differential pressure sensor for high pressures up to 100 MPa was not commercially available. Instead, a pair of accurate absolute pressure transducers was used as a differential pressure sensor and the pressure drop was calculated by subtracting the outlet pressure from the inlet pressure with a resolution of 100 Pa at 100 MPa. The apparatus provided viscosities of hydrogen from ambient temperature up to 400 K and for pressures up to 100 MPa with a maximum deviation of 2.2%. Another way to measure the viscosity of hydrogen gas is by a vibrating wire method [142]. The viscosity of hydrogen at temperatures of 296–573 K and under pressures of up to 0.7 MPa were measured by a vibrating wire method with an uncertainty of 1.4% [143].

### 2.10.3 Flow Properties of Slush Hydrogen

While it is relatively easy to measure flow properties of a homogeneous fluid, measuring viscosity of a two-phase heterogeneous suspension of solid hydrogen in liquid hydrogen is a more difficult task. Slush hydrogen pressurized expulsion tests were performed to provide experimental data on pressurant gas requirements, ullage and tank wall temperature distributions, and slush hydrogen density changes. The tests used gaseous hydrogen pressurant during the expulsion of normal boiling point liquid hydrogen and slush hydrogen from a 1.89-m<sup>3</sup> (500-gallon) spherical tank. Expulsion test data obtained for the slush hydrogen and normal boiling point hydrogen experiments were compared with predictions from an analytical model. A computer program (EXPL) was used to model pressurant gas requirements, 1-D wall and ullage gas temperatures, and slush hydrogen density changes during pressurized expulsion.

## 2.11 Surface Tension of Hydrogen

Surface tension data of liquid normal hydrogen are listed in Table 18 and illustrated in Figure 25.

**Table 18:** Surface tension of normal, liquid hydrogen.

| Temperature, K | Surface tension |        |
|----------------|-----------------|--------|
|                | N/m             | dyn/cm |
| 13.0           | 0.00349         | 3.49   |
| 15.0           | 0.00313         | 3.13   |
| 20.0           | 0.00223         | 2.23   |
| 25.0           | 0.00133         | 1.33   |

Data source: [144]

The surface tension as a function of temperature is a linear function and can be calculated from

$$\sigma = 5.83 - 0.18 T$$

where  $\sigma$  is the surface tension in dyn/cm and  $T$  is the absolute temperature in kelvin. This equation is similar to

$$\sigma = \sigma_0 - \left(1 - \frac{T}{T_c}\right)$$

where  $\sigma$  is the surface tension in dyn/cm,  $\sigma_0$  is 5.328 for parahydrogen, and 5.369 for normal hydrogen,  $T$  is the temperature in kelvin, and  $T_c$  is the critical temperature.  $T_c$

is 32.976 K for parahydrogen and 33.18 K for normal hydrogen. The surface tension of liquid parahydrogen is 0.0029 N/m at the triple point and 0.00193 N/m at the normal boiling point. The surface tension of liquid normal hydrogen is 0.003 N/m at the triple point and 0.00195 N/m at the normal boiling point. The surface tension of parahydrogen is illustrated in Figure 24.

**Figure 24:** Surface tension of parahydrogen. (Reproduced and modified from [41].)

For temperatures higher than about 21 K only the measurements by Blagoi and Pashkov on normal hydrogen are available [145]. In the temperature range below 26–27 K, the surface tension can be calculated from

$$\sigma = 5.38 - 0.170T \pm 0.02$$

where  $\sigma$  is the surface tension in dyn/cm and  $T$  is the temperature in kelvin. These data are illustrated in Figure 25.

A comparison of the measurements by Blagoi and Pashkov on normal hydrogen with the equations proposed by Corruccini showed that extrapolation of the equations to temperatures above about 22 K leads to sizeable differences at the higher temperatures. Table 19 is a comparison of the Corruccini data and the Blagoi and Pashkov data. The Blagoi and Pashkov data are consistently about  $70 \times 10^{-6}$  N/m (0.07 dyn/cm) lower at all temperatures below 31.5 K than those calculated from the above equation and are considered not very accurate. See also [146].

**Figure 25:** Surface tension of hydrogen. (Chart created by Schmidt 2021 based on numerical data from [145].)

**Table 19:** Comparison of surface tension of hydrogen data.

| Data source                   | Corrucini [75]           |                          | Blagoi and Pashkov [145] |        |       |        |
|-------------------------------|--------------------------|--------------------------|--------------------------|--------|-------|--------|
|                               | <i>p</i> -H <sub>2</sub> | <i>n</i> -H <sub>2</sub> | <i>n</i> -H <sub>2</sub> |        |       |        |

## 2.12 Thermal Conductivity of Hydrogen

### 2.12.1 Thermal Conductivity of Solid Hydrogen

The thermal conductivity of solid hydrogen, similar to the heat capacity, is highly dependent on the orthohydrogen-parahydrogen composition. It also depends on crystal quality and on density for the compressed solid states. Most of the measurements were made at or near saturation pressure. The thermal conductivity of solid 99% parahydrogen with 1% orthohydrogen is at a maximum at 4 K. Some of the data reported in the literature differed by almost an order of magnitude. The thermal conductivity of solid hydrogen must be known to predict the behavior of hydrogen particles in hydrogen slush as they freeze or melt.

The thermal conductivity of solid  $p\text{-H}_2$  was measured under three sets of conditions, ranging from 8.92 MPa (88 atm) pressure at 15 K to 20.37 MPa (201 atm) at 17 K [100]. These thermal conductivity data, combined with values from the literature, are shown in Figure 26. From this figure it can be seen that the thermal conductivity of solid  $p\text{-H}_2$  changes very little with an increase of either temperature or pressure at temperatures above 11 K. All three measured values fall in the range 0.086–0.0100  $\text{W cm}^{-1} \text{K}^{-1}$ . It can be seen that the values in this range are about four times as high as those for liquid  $p\text{-H}_2$ . The curves in Figure 26 are similar to those

Figure 26: Thermal conductivity of solid hydrogen. (Reproduced and modified from [100].)

shown in Figure 42 on page 5–46 of [41], except that the graph also shows data for hydrogen containing 10, 29, 55, and 72% orthohydrogen and also for deuterium, as shown here in Figure 27. Deuterium is not used as a rocket propellant, but it may be used in chemical lasers. The two curves based on data from two different authors for hydrogen with 1% orthohydrogen differ by almost an order of magnitude. This chart is very busy and should have been separated into one for hydrogen and one for deuterium.

**Figure 27:** Thermal conductivity of solid hydrogen. (Reproduced and modified from [41].)

Legend: H.S. = Hill and Schneidmesser 1958; B.M. = Bohn and Mate 1970; D.C.B. = Dwyer, Cook, and Berwaldt 1966

Hill and Schneidmesser [147] published measurements of the thermal conductivity of solid hydrogen as a function of its  $o\text{-H}_2$  content. The  $o\text{-H}_2$  concentration was not determined analytically, but was inferred from the method of preparation; no further details were given.

The thermal conductivity of solid parahydrogen containing 0.2–5% orthohydrogen was measured over the temperature range 1.5–6 K [148]. On the low-temperature side of the conductivity maximum, the conductivity showed both a  $T^3$  dependence and a strong dependence on orthohydrogen concentration.

### 2.12.2 Thermal Conductivity of Liquid Hydrogen

The thermal conductivities of liquid normal and liquid parahydrogen have been measured over the temperature interval 13–27 K [87]. They were found to be independent of the orthohydrogen-parahydrogen composition and can be expressed by the equation

$$k = (1.702 + 0.05573T) \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ }^\circ\text{C}^{-1}.$$

It was believed that the probable error was within 2%, but later examination showed that the Powers, Mattox, and Johnston 1954 [87] data were substantially higher than the more accurate numbers measured later.

Taking thermal conductivity data for liquid hydrogen from almost a dozen different quite antiquated sources and plotting them against the reduced temperature normalized by the critical temperature (33.3 K) gives an almost linear relationship as shown in Figure 28 [149].

For data on the thermal conductivity of liquid hydrogen see also [150]. The thermal conductivity of gaseous and liquid hydrogen has been measured with a guarded horizontal flat-plate calorimeter at temperatures between 17 and 200 K and at pressures up to 15 MPa [70, 151]. The data have been analyzed as a function of density at fixed temperatures and as a function of temperature at fixed densities. Outside the critical region the thermal conductivity of both the gas and the liquid increases continuously with temperature and density. In the compressed liquid the temperature derivative at fixed density is positive and unusually large compared to that for most other simple liquids. In the critical region the thermal conductivity increases rapidly with both temperature and density as these parameters approach their critical values.

The thermal conductivity of liquid hydrogen depends on temperature and is particularly sensitive to density. Its behavior is related to that of  $C_v$  and  $C_p$ . For temperatures up to the critical point the thermal conductivity shows very little dependence on orthohydrogen-parahydrogen composition. Values for the thermal conductivity of liquid hydrogen are uncertain by about 3%. Differences in experimental values reported by various investigators have been attributed to convection.

Surveys of information on hydrogen thermal conductivity also included hydrogen isotopes [70]. The thermal conductivities of liquid and gaseous hydrogen are illustrated in Figure 29. The difference between the two physical states diminishes as the temperature approaches the critical point. Similar data are available for the other two hydrogen isotopes.

**Figure 28:** Thermal conductivity of liquid hydrogen versus reduced temperature. (Reprinted and adapted from [149], with permission from ©1958 American Chemical Society; permission conveyed through RightsLink.)

The thermal conductivity of liquid parahydrogen was measured at temperatures from 15.4 to 21.4 K at pressures from below atmospheric to 21.8 MPa (215 atm), [100]. All measured thermal conductivities for liquid  $p$ -H<sub>2</sub> were in the range from 0.0014 to 0.0036 W cm<sup>-1</sup> K<sup>-1</sup>.

Fundamental transport properties of liquid paraparahydrogen ( $p$ -H<sub>2</sub>), i.e., thermal conductivity, diffusion coefficients, shear viscosity, and bulk viscosity, have been evaluated over a wide temperature range, 14–32 K, by means of path integral centroid molecular dynamics (CMD) calculations [131]. Although a relatively large deviation was found for the thermal conductivity, the calculated values are less than three times the amount of the experimental values at any temperature. From the comparison based on the principle of corresponding states, it has been shown that the marked deviation of the transport properties of liquid  $p$ -H<sub>2</sub> from the properties expected from the molecular parameters is due to the quantum effect.

**Figure 29:** Thermal conductivity of liquid and gaseous hydrogen. (Reproduced and modified from [70].)

A survey of experimental data for the thermal conductivity and viscosity of hydrogen, physical properties which are needed for many applications in system analysis and design, included an analysis of the current standard models for thermal conductivity and viscosity of normal hydrogen and parahydrogen, which are based on measurement and correlation work done before the mid-1980s, and collected more than 100 literature references on transport properties of hydrogen and a few on transport properties of parahydrogen [132]. Properties calculated with these models were analyzed and compared to all available experimental data for normal hydrogen and parahydrogen, and percent deviations of individual data sets from the computed mean were graphed.

Thermal conductivity measurements of subcooled equilibrium liquid hydrogen in the temperature range from 15 to 23 K and under pressures up to 1 MPa were done in a horizontal, guarded, flat-plate calorimeter [152], Figure 30. One-dimensional heat transfer between the hot and the cold plates of the calorimeter was achieved by the placement of two thermal guards. Capacitance measurement between the calorimeter plates gave a precise and accurate value for the gap. Knowledge of the density

dependence on the thermal conductivity is useful for subcooled hydrogen transport processes. One should note that the distinction between equilibrium hydrogen and parahydrogen is insignificant in this case as equilibrium hydrogen is 99.8+% parahydrogen in the indicated temperature range. Writers often refer to liquid hydrogen with the implication that it is in the equilibrium state. The addition of uncertainty bars to Figure 30 makes it a little more difficult to read data.

**Figure 30:** Thermal conductivity of liquid hydrogen measurement results at constant pressures. (Reprinted and modified from [152] with the permission of ©2008 AIP Publishing)

A correlation of the thermal conductivity of liquid normal and parahydrogen from the triple point to 1000 K and up to 100 MPa contains a list of 13 primary data sources and 40 secondary data sources of thermal conductivity of hydrogen from the literature [153]. The literature data were fitted into a set of correlation equations and their deviations from the calculated mean were shown. The equations were based in part on a body of experimental data that has been critically assessed for internal consistency and for agreement with theory whenever possible. Figure 31 shows a plot of the thermal conductivity of normal liquid hydrogen values calculated by 7 different equations for the temperature range 14–150 K for pressures between 0 and 50 MPa. Note that the units on the abscissa scale shown in Assael et al. 2011 should be  $mW K^{-1} m^{-1}$  and not  $W K^{-1} m^{-1}$ .

**Figure 31:** Thermal conductivity of normal hydrogen as a function of the temperature for different pressures. (Republished and modified from [153], with permission of ©2011 American Institute of Physics; permission conveyed through Copyright Clearance Center Inc.)

Figure 32 shows the thermal conductivity of liquid parahydrogen as a function of density for two isotherms that exhibit critical enhancement. The model is shown with and without the critical enhancement term. The experimental data of Roder and Diller 1970 are plotted at nominal isotherms of 33 and 40 K using the experimental values of temperature and density.

The thermal conductivity of a classical fluid is a function of the density  $\rho$  and the temperature  $T$ . Various molecular theories of thermal conductivity including those based on a pseudo-lattice model of the liquid state have been examined to determine whether they predict the sign and magnitude of the separation of the low-temperature isotherms [154]. They can only be applied to the dense fluid as the relevant deviations also occur at low temperatures and high densities. The lattice theories have been used to explain the thermal conductivities of simple liquids below the critical temperature, where they are relatively small.

### 2.12.3 Thermal Conductivity of Gaseous Hydrogen

The thermal conductivity of hydrogen gas depends primarily on temperature and on density or pressure (Table 20).

**Figure 32:** Thermal conductivity of parahydrogen as a function of density for 33 and 40 K isotherms. (Republished and modified from [153], with permission of ©2011 American Institute of Physics; permission conveyed through Copyright Clearance Center Inc.)

**Table 20:** Calculated thermal conductivity of gaseous hydrogen at 1atm.

| Temperature<br>K | Thermal conductivity             |                                                               |
|------------------|----------------------------------|---------------------------------------------------------------|
|                  | $\text{mW m}^{-1} \text{K}^{-1}$ | $\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1} \times 10^6$ |
| 10               | 5.98                             | 14.3                                                          |
| 20               | 14.48                            | 34.6                                                          |
| 30               | 22.38                            | 53.5                                                          |

Data source: [61]

The thermal conductivity of gaseous normal hydrogen at 1 atm for the range from 20 to 2000 K can be calculated from the following equation [134]:

$$\lambda = \left( 1.8052 T - 1.4829 \times 10^{-3} T^2 + 1.2481 \times 10^{-6} T^3 - 4.195 \times 10^{-10} T^4 + 4.6302 \times 10^{-14} T^5 \right) \times 10^{-6}$$

where  $T$  is the temperature in kelvin and  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$ .

The thermal conductivity of gaseous parahydrogen and normal hydrogen diverge in the range from 100 to 250 K. The ratios of the two thermal conductivities are listed in Table 21 and illustrated in Figure 33.

**Figure 33:** Thermal conductivity of gaseous parahydrogen and normal hydrogen. (Reproduced and modified from [144], based on data from Farkas 1935.)

**Table 21:** Ratio of thermal conductivities of gaseous normal and parahydrogen

| Temperature, K | Ratio $\lambda_p/\lambda_n$ |

Data source: [144]

For temperatures below the critical point the dependence on orthohydrogen-parahydrogen composition is only very slight ~0.5%, but the difference reaches a maximum at 160 K (Figure 34). The difference in thermal conductivity can be used to analyze the parahydrogen content of hydrogen gas.

The difference in thermal conductivity between parahydrogen and normal hydrogen, noticeable only in a narrow range between 100 and 300 K, can be used for the determination of parahydrogen content in hydrogen gas samples. One must make sure that no catalysts are in the thermal conductivity measurement apparatus, otherwise the composition of the sample would change while the measurement is in progress. The gas flow could be measured first, then passed over a catalyst to allow it to equilibrate, and then measured again. This can be done with a pair of thermistors in a Wheatstone bridge circuit.

The thermal conductivity of hydrogen was determined indirectly from measured effective thermal conductivities of porous tungsten specimens in a pressurized hydrogen atmosphere. Measurements were made at pressures of 1.03, 0.69, 0.34, and 0.1 MPa (150, 100, 50, and 15 psia) and at temperatures to 2866 K (4700 °F) [155, 156].

The thermal conductivity of liquid hydrogen rises infinitely steep at the critical point (Figure 35). The auxiliary parameter shown in line with the curves is the pressure in MPa. The thermal conductivity of liquid parahydrogen at the triple point is  $0.7259 \text{ mW cm}^{-1} \text{ K}^{-1}$ , and it is  $0.9892 \text{ mW cm}^{-1} \text{ K}^{-1}$  at the normal boiling point. The thermal conductivity of normal liquid hydrogen is the same as that of parahydrogen. The thermal conductivity of gaseous hydrogen is  $0.1243 \text{ mW cm}^{-1} \text{ K}^{-1}$  at the triple point and  $0.1694 \text{ mW cm}^{-1} \text{ K}^{-1}$  at the normal boiling point.

Thermal conductivity measurements of normal, near normal, parahydrogen, and parahydrogen-rich hydrogen were made with a transient hot wire apparatus over the temperature range from 78 to 310 K with pressures to 70 MPa and densities from 0 to

**Figure 34:** Differences in thermal conductivity between parahydrogen and normal hydrogen. (Invariant with pressure, reproduced and modified from [41].)

**Figure 35:** Thermal conductivity of parahydrogen. (Reproduced and modified from [41].)

a maximum of 40 mol/L [157, 158]. For compositions normal and near normal, the isotherms covered the entire range of pressure, and the temperatures were 78, 100, 125, 150, 175, 200, 225, 250, 275, 294, 300, and 310 K. The  $p$ -H<sub>2</sub> measurements included eight isotherms at temperatures from 100 to 275 K with intervals of 25 K, pressures to 12 MPa, and densities from 0 to 12 mol/L. Three additional isotherms at 150, 250, and 275 K covered  $p$ -H<sub>2</sub>-rich compositions with parahydrogen percentages varying from 85 to 72%. The data for all compositions are represented by a single thermal conductivity surface.

Calculations of the viscosity and thermal conductivity coefficients of normal hydrogen in the limit of zero density as a function of temperature were based upon the semi-classical kinetic theory of polyatomic gases and a body of critically evaluated experimental data [159]. The available thermal conductivity data of high accuracy cover the much more restricted temperature range from 100 to 400 K and the correlation of this property is limited to that range. An attempt has been made to represent the viscosity data by means of a correlation universal among several other polyatomic gases but it has proven unsatisfactory for hydrogen. An extension of the temperature range of the thermal conductivity correlation based upon the Wang, Chang, and Uhlenbeck kinetic theory also failed to produce acceptable results.

The thermal conductivity for normal hydrogen gas was measured in the range of temperatures from 323 to 773 K at pressures up to 99 MPa using a transient short hot-wire method [160]. An existing thermal conductivity equation of state was modified to include the expanded range of conditions measure. The new correlation is applicable from 78 to 773 K with pressures to 100 MPa and is in agreement with the majority of the reported thermal conductivity measurements within  $\pm 2\%$ .

The thermal conductivities and thermal diffusivities of hydrogen gas were measured with a transient short hot-wire method for temperature range up to 573 K (300 °C) and pressure range up to 100 MPa [161]. The measured thermal conductivities showed good reproducibility and agreed with the existing values within a deviation of  $\pm 2\%$ . See also [71, 73].

#### 2.12.4 Thermal Diffusivity of Hydrogen

The thermal diffusivity,  $\alpha$ , is defined as

$$\alpha = \frac{\lambda}{\rho C_p}$$

where  $\alpha$  is the thermal diffusivity in m<sup>2</sup>/h,  $\lambda$  is the thermal conductivity in J s m<sup>-1</sup> K<sup>-1</sup>,  $\rho$  is the density in kg/m<sup>3</sup>, and  $C_p$  is the heat capacity in J kg<sup>-1</sup> K<sup>-1</sup>. The thermal diffusivity of liquid hydrogen at the triple point is 0.00053 m<sup>2</sup>/h and at the boiling point it is 0.00052 m<sup>2</sup>/h. The thermal diffusivity of hydrogen gas at the triple point is 0.034 m<sup>2</sup>/h and at the boiling point it is 0.0038 m<sup>2</sup>/h.

## 2.13 Heat Transfer Coefficient of Hydrogen

### 2.13.1 Heat Transfer Coefficient to Liquid Hydrogen

The heat transfer to hydrogen, in particular heat transfer to liquid hydrogen, which is important for the design of regeneratively cooled chemical combustion chambers or nuclear-thermal rocket heat exchangers, has been thoroughly studied during the past 70 years.

While the heat transfer characteristics of other cryogenic and non-cryogenic liquids such as ammonia or liquid oxygen have been known for a long time, the corresponding data for hydrogen only became available after the interest in hydrogen as a rocket propellant increased 70 years ago. Like so many other physical properties, the heat transfer properties of hydrogen are somewhat abnormal. The fundamentals of heat transfer are textbook knowledge and most third year chemical engineering students will master them. We may assume that this basic understanding pre-exists with most of the readers of this chapter.

Although this book deals mostly with chemistry and not the physics of propellants, we found it useful to compile references to design equations for rocket engines with regeneratively cooled chambers and nozzles. This should be a great help to the rocket designer. Thermal conductivity measurements try to eliminate gravity-dependent effects like convection. Heat transfer measurements depend on the conditions of convection and the absence or presence of gravity. We deal with free (density gradient) convection and forced convection [162]. A review of forced convection and natural convection processes in low-temperature (cryogenic) fluids placed the emphasis on forced convection, including turbulent forced convection, because more applications for that type of cooling are found. Transport properties of a near-critical fluid and the effects of curvature on the properties of near-critical hydrogen need to be known. Theoretical considerations in free and forced convection were examined. For stagnant fluids, we need to know the free heat transfer in varying gravitational fields, on Earth and in orbit. For forced convection, the flow velocity and its Reynolds number (laminar vs. turbulent flow) and the heat flux determine different regimes of heat transfer (nucleate and film boiling). The understanding of free convection heat transfer is needed to calculate the evaporation losses from stationary ground storage tanks and flight tanks during the pre-launch hold.

There are many publications which provide a good summary of heat transfer properties of liquid hydrogen, including [163–168]. Because the heat of evaporation of liquid hydrogen is relatively low, it does not take much heat input to convert liquid to gas. This occurs in many rocket engine cooling jackets and in specially designed gas generators where the liquid is injected into hot combustion products to generate hot gas to drive a turbine (which in turn drives the propellant pumps). In most rocket engines with hydrogen the hydrogen enters the combustion chamber in the gaseous or supercritical state.

In the early days of computers (main frame computers), a FORTRAN program (remember punch cards?) was written that permitted calculation of real fluid state relations, thermodynamic properties, and transport properties of molecular hydrogen in any fixed orthohydrogen-parahydrogen combination [169]. The program was to be used for numerical integration of heat transfer and fluid-flow calculations over the temperature range from melting to dissociation for pressures up to 34.4 MPa (340 atm = 5000 psia). A more recent computer program was developed for calculation of thermal and transport properties of parahydrogen from 20 to 10000 K and a pressure range from 10 kPa to 16 MPa [170].

A technique for obtaining the transient heating, cooling, and freezing heat transfer characteristics of liquid hydrogen is based on the magnetocaloric effect [171]. This method takes advantage of the reversible change in temperature exhibited by certain magnetic materials as they experience increasing or decreasing magnetic fields. A single crystal of paramagnetic gadolinium gallium garnet was placed in a temperature-regulated chamber which could be filled with liquid hydrogen. The temperature of the crystal was monitored as it experienced relatively rapid increasing or decreasing magnetic field strengths in vacuum or in the presence of liquid hydrogen. The results of a one-dimensional finite difference model were compared to the data to yield the transient heat transfer characteristics.

### 2.13.1.1 Heat Transfer in the Free Convection Regime

The graph showing heat flux per unit area ( $q/A$ ) as a function of the temperature differential between the wall and the liquid ( $T_w - T_s$ ) (the so-called boiling curve) passes through an initially flat zone (pure convection) and then traverses a steeper slope (bubble formation, nucleate boiling) and finally reaches a maximum at the upper limit of nucleate boiling. Above that is an unstable (oscillating) intermediate zone before the zone of stable film boiling is reached.

For calculating the evaporation losses of liquid hydrogen during storage in stationary tanks, we will initially only look at the first two regimes, those of pure convection and incipient nucleate boiling. For the regime of pure convection, the relationship between dimensionless numbers is as follows:

$$\text{Nu} = 0.54(\text{Gr Pr})^{1.25}$$

and

$$\text{Gr} = \frac{g\beta D^3 \Delta T}{\nu^2}$$

where Nu is the Nusselt number, Gr is the Grashof number, and Pr is the Prandtl number. Further,  $g$  is the gravity acceleration,  $\beta$  is the coefficient of thermal expansion (equal to approximately  $1/T$ , for ideal gases),  $D$  is the diameter,  $\Delta T$  is the difference in temperature, and  $\nu$  is the kinematic viscosity.

For the regime of incipient nucleate boiling different authors propose different equations, which differ in the definition of the characteristic diameter  $D$ . A good summary of these equations is given in a publication in which the discussion is extended to higher temperature differentials which are normally not encountered in liquid hydrogen storage tanks [166].

Natural convection heat transfer and heat transfer for the point of inception of vapor formation for liquid hydrogen and liquid nitrogen, and nucleate boiling heat transfer in liquid hydrogen were measured, and some data indicated a hysteresis effect with increasing and decreasing heat flux [172]. The variables studied were heater surface material, roughness, and orientation.

Instead of measuring heat transfer to cylindrical tank walls or tubes, it is easier to formulate the maths for heat transfer to and from a flat plate immersed in liquid hydrogen [173]. Equations derived from this geometry can be used for calculating evaporation losses from other more complex geometrical shaped tanks [174].

The start of bubble nucleate boiling in stagnant liquid hydrogen on a horizontal heater was observed visually as a function of pressure in the pressure range  $p = 7.2 \times 10^3$  to  $6 \times 10^5$  Pa and with heat fluxes of 640–2120 W/m<sup>2</sup> in an apparatus similar to that one used earlier by Coeling [172, 175].

### 2.13.1.2 Heat Transfer during Nucleate Boiling

Nucleate boiling does not start until the hot convecting fluid finds a seed which can be a dust particle or an irregularity in the wall. Until the first bubble forms, the liquid is in a locally superheated state [176]. The metastable superheat  $\Delta T$  attainable by a liquid above its saturation temperature is important in determining the onset of nucleate boiling. Aside from the boiling description, however, a knowledge of  $\Delta T$  also provides criteria for heat transport transition when bubble formation is entirely suppressed. A non-boiling liquid may be heated to the maximum metastable superheat before it disintegrates. As soon as the wall excess temperature increases beyond the limiting superheat value, the system will enter the Leidenfrost film boiling regime, within which liquid is converted into the completely disordered phase when it approaches the hot walls. Polished surfaces are more likely to lead to superheat and delayed nucleate boiling.

Various heat transfer mechanisms including convection, transient conduction, and evaporation contribute to the overall nucleate-boiling heat flux. A nucleate-boiling model was proposed that applies to any boiling liquid, including liquid hydrogen, and included elements of each of the aforementioned mechanisms. From a comparison of the model with experimental information on water and methanol, no single mechanism dominates over the entire boiling heat-flux range. The cyclic removal of heat from the surface into the liquid sublayer by conduction appears to be an efficient process compared with steady-state free convection [177].

With boiling of liquid hydrogen under increasing pressure one observes a shift of the  $q$ - $\Delta T$  curves to higher values of  $\Delta T$ , caused by a layer of immobilized gases,

the thickness of which increases continuously. The departure diameter  $D$  and the frequency  $f$  of bubbles were observed with discrete nucleate boiling under pressure [178]. The results can be described by the equation  $fD^2 = K$ . The constant  $K$  gets smaller with rising pressure and with increasing roughness of the surface.

### 2.13.1.3 Transition from Nucleate to Film Boiling

Early experimental studies on boiling heat transfer to liquid hydrogen involved the measurement of heat fluxes and wall temperatures only where they studied both the nucleate and film boiling regimes but did not correlate their data. Hendricks et al. [179, 180] studied the film boiling regime only and assumed an annular flow model and vapor-liquid equilibrium. In an attempt to use earlier correlations to predict fluid and wall and fluid qualities, significant discrepancies were found between observed and predicted values [181].

In order to measure the onset of nucleate and film boiling resulting from transient heat transfer to liquid hydrogen, thin carbon films and Pt foils submerged in liquid hydrogen received stepped inputs of power of 1–42 W/cm<sup>2</sup>, and the onset of nucleate or film boiling was obtained for each power level [182, 183]. A single device used as both heater and thermometer eliminates any temperature difference and time lags in heat transfer between the heater and thermometer. Devices constructed of  $4 \times 10^{-4}$  cm thick Pt foil, a well-characterized thermometric material, adhered to quartz and fiberglass-epoxy substrates, had good sensitivity and fast response at 20 K. The critical heat flux was found to be approximately 8 W/cm<sup>2</sup>, with the transition to film boiling occurring in times less than 1 ms. Premature film boiling can be related to the positive temperature coefficient of resistance and the narrowness of the heaters.

Heat transfer from a flat plate facing upward immersed in a liquid hydrogen pool was measured for pressures from atmospheric to 1.1 MPa [184]. Critical heat fluxes in saturated boiling increased with the increase in pressure up to around 0.3 MPa and then decreased with further pressure increase. The critical heat fluxes under subcooled conditions at each pressure increased with the increase in subcooling. The experimental critical heat fluxes were much smaller than those predicted for higher pressure up to critical pressure. The heater surface temperature was found to reach the critical temperature before the occurrence of hydrodynamic instability and transition to the film boiling regime at the lower heat flux in the higher pressure range.

Transient heat transfer from a horizontal flat plate in a pool of liquid hydrogen was measured under saturated and subcooled conditions at pressures from 104 to 700 kPa [185]. Transient heat transfer before the inception of boiling for exponential periods shorter than 100 ms was expressed well by the transient conduction heat transfer with no movement of liquid. Incipient boiling heat flux and temperature were higher for shorter transient periods. Transient critical heat flux was higher for shorter exponential periods and higher subcooling.

Film boiling heat transfer properties of LH2 under various pressure and subcooling conditions were measured by applying electric current to a horizontal PtCo wire

with a diameter of 1.2 mm submerged in LH2 to give an exponential heat input [186]. The heat transfer coefficient in the film boiling region was higher for higher pressure and higher subcooling. The experimental results were compared with predictions from literature equations for pool film boiling heat transfer, and good agreement was observed.

#### 2.13.1.4 Effect of Gravity and Acceleration on the Rate of Hydrogen Evaporation

Because liquid hydrogen is stored not only on the surface of Earth but at times is stored for short periods in space under conditions of complete or partial weightlessness, it is important to know heat transfer properties at reduced or non-existent gravity. At the other extreme of acceleration, heat transfer to hydrogen during periods of high acceleration during the launch of rockets must be understood. Initially, this concerned only liquid hydrogen that was carried in upper stages such as CENTAUR, the S-II or the S-IVB, but now liquid hydrogen is used in many booster stages (ARIANE, H-II, DELTA-IV, SLS) and it was carried in the Space Shuttle external tank.

#### 2.13.1.5 Heat Transfer in Zero $g$ and Low $g$

Visual observation of heat transfer to boiling liquid hydrogen in zero  $g$  showed that the heat transfer is very similar to that at 1  $g$ . Zero  $g$  nucleate boiling heat transfer tests were performed to study the action of boiling liquid hydrogen on the face of a heated surface and to determine the heat flux as a function of the temperature in both 1  $g$  and zero  $g$  environments [187]. Visual observation of boiling for a range of heat fluxes between 788.6 and 22082 W/m<sup>2</sup> (250 and 7000 BTU h<sup>-1</sup> ft<sup>-2</sup>) showed that the bubbles formed at the heated surface coalesced and the surface tension forces were sufficient to rewet the surface behind the bubble. Data indicated that the zero  $g$  nucleate boiling heat transfer is approximately the same as 1  $g$  boiling heat transfer results for the particular test specimen orientation used throughout the tests and for the zero  $g$  test duration times available.

It could be seen that bubbles separate from the surface and that the surface is immediately again wetted by liquid hydrogen [188]. These observations were made in a jet plane flying a parabolic flight path that provides near-zero gravity for only a few minutes.

More realistic heat transfer data were obtained during the flights of CENTAUR and SATURN S-IVB upper stages [189–192]. Theoretically one would expect a dependence of the heat transfer with free convection on the acceleration, be it gravity or flight-induced, because  $g$  enters into the Grashof number. In the absence of gravity, density gradients will no longer cause convection currents. These considerations apply not only to liquid hydrogen under zero  $g$ , but they are examining the behavior of liquid oxygen under zero  $g$  as well. See also [193].

Incipient and steady boiling of cryogenic liquids, both LN2 and LH2, under reduced gravity conditions was studied in a drop tower which had 9.7 m (32 ft) free fall distance, giving 1.34 s of free fall [194]. The parameters varied included the fluid used,

heater surface temperature, geometry, orientation, and fractional gravity. A transient calorimeter technique was used with a variety of geometries. This technique readily provided results in all of the boiling regimes. The transient calorimeter technique was adapted to flat surfaces to determine the influence of geometry and orientation on boiling of LN2 and LH2 at normal and reduced gravities. A vertical cylinder was used to simulate a vertical flat plate. Measurements of incipient boiling at normal and zero gravity were made in both LN2 and LH2, using a transient technique with a platinum wire. A step increase in power was applied, and from the transient wire temperature measurements it was possible to observe when nucleate boiling began. It was observed, in both LN2 and LH2, that the maximum heater superheat at nucleation was independent of the body forces present.

An existing gravity scaling analysis, proposed based on the experimental data of non-cryogenic fluids, was assessed using the boiling heat transfer data of hydrogen under different gravities [195]. A validation study showed that this scaling analysis is also acceptable in predicting the nucleate boiling heat transfer of hydrogen under low gravity conditions. Through this analysis, the heat flux at any gravity level can be obtained if data in a similar condition are available at a reference gravity. Another scaling analysis aiming at the film boiling regime was proposed, and its predictive accuracy was validated by comparing its predictions with hydrogen experimental data. The comparison showed that a reasonable agreement was obtained and the deviation was within 15%. Hydrogen boiling curves under normal gravity and microgravity conditions were constructed which showed that microgravity yields lower heat flux throughout the overall boiling range, and the influence of gravity on heat flux is most significant in the film boiling regime.

The flow boiling of liquid hydrogen during transfer in microgravity is very different from that under terrestrial conditions. A saturated flow boiling of LH2 in a horizontal tube has been modeled under microgravity conditions using coupled level-set and volume of fluid methods [196]. The validation of the developed model showed good agreement with experimental data from the literature. The changes of heat fluxes and pressure drops under different gravitational accelerations were analyzed. The variation of heat fluxes with different wall superheat and contact angle were compared between microgravity ( $10^{-4}g_0$ ) and normal gravity ( $1g_0$ ) conditions where the influence of surface tension under microgravity was considered. The numerical results indicated that the heat flux decreased with the decrease of gravitational acceleration. The heat transfer ratio decreased with the increase of wall superheat in the nucleate boiling regime. The heat transfer was slightly reduced when considering surface tension. The changes of contact angle may have a more significant impact on heat transfer under microgravity condition than surface tension alone.

#### **2.13.1.6 Heat Transfer at High Accelerations**

Heat transfer to boiling liquid hydrogen was measured with samples on a centrifuge at accelerations up to 10g [197–199]. The influence of gravity on nucleate boiling heat

transfer is not as strong as that of tank pressure; however, in the film boiling regime acceleration has a more pronounced effect than in the nucleate boiling regime.

### 2.13.1.7 Heat Transfer in the Regime of Forced Convection

The achievable heat fluxes in the regime of forced convection (e.g. flow through a heated pipe or a flat or annular channel) are several orders of magnitude higher than in free convection and are often encountered in the regenerative cooling channels of rocket engines. The shape of the boiling curve with its characteristic regimes of convection, nucleate boiling, partial film boiling and total film boiling is similar to that of free convection heat transfer, but the entire curve is shifted toward higher  $q/A$  fluxes. The dependence of heat transfer on the flow velocity is least in the regime of nucleate boiling.

A single-tube heat transfer apparatus was used to determine heat transfer coefficients to boiling liquid hydrogen [200]. The facility set-up allowed measurements to be made at pressures up to 276 kPa (40 psia) and flow rates up to about 2.26 kg/min. (5 lb<sub>m</sub>/min.) through a 6.3-mm (0.25-in.) ID test section at saturated liquid Reynolds numbers from 220000 to 660000 at pressures from 162 to 223 kPa (1.6–2.2 atm).

Boiling heat transfer to liquid hydrogen under conditions of forced flow inside a vertical tube under a wide range of operating variables (flow rate, pressure, liquid inlet subcooling, heating rate and tube geometry, i.e., length to diameter ratio), the mode of heat transfer and their relation to the value of the critical heat flux were compared to similar tests with liquid nitrogen [201], Table 22. The test apparatus consisted of a pressure-fed, once-through system with an electrically heated vertical tube of 14 mm (0.555 in.) internal diameter and 40.6 cm (16 in.) length. Subcooled liquid parahydrogen or liquid nitrogen flowed through the tube in vertical up-flow. Tube exit qualities ranged from essentially 0–1.0 (with superheat), and transition from a relatively high to a lower value of heat transfer coefficient occurred over a range of axial locations from tube entrance to exit. The critical heat flux corresponds to the local heat flux just upstream of the location of a sudden rise in wall temperature.

**Table 22:** Heat transfer conditions tested at NASA

|                                                       | Hydrogen        | Nitrogen       |
|-------------------------------------------------------|-----------------|----------------|
| Mass velocity, lb h <sup>-1</sup> ft <sup>-2</sup>    | 2850 to 17000   | 15000 to 56000 |
| Mass velocity, lb h <sup>-1</sup> m <sup>-2</sup>     | 264.8 to 1580   | 1394 to 5204   |
| Mass velocity, kg h <sup>-1</sup> m <sup>-2</sup>     | 120 to 716      | 631 to 2358    |
| Local heat flux, BTU h <sup>-1</sup> ft <sup>-2</sup> | 3600 to 40000   | 2300 to 40000  |
| Local heat flux, W/m <sup>2</sup>                     | 11356 to 126483 | 7255 to 126483 |
| Liquid inlet subcooling, °R                           | 0 to 9          | 1 to 6         |
| Liquid inlet subcooling, K                            | 0 to 5          | 0.5 to 3.3     |
| Inlet pressure, psia                                  | 30 to 74        | 47 to 56       |
| Inlet pressure, kPa                                   | 206 to 510      | 324 to 386     |

Data source: [201]

In the regime of non-boiling forced convection heat transfer in flowing liquid hydrogen, the heat flux can be expressed by a DITTUS-BOELTER equation [202, 203]

$$\text{Nu} = 0.016\text{Re}^{0.8}\text{Pr}^{0.4}$$

A comparison of heat transfer at nucleate and film boiling for free convection versus forced convection showed that boiling heat fluxes for vertical flow and horizontal flow at comparable pressures showed very little observable effect of the orientation [204]. Pool boiling data for the film boiling and nucleate boiling regimes were compared to other flux vs.  $T_W - T_L$  correlations and there was some similarity in the slope of the curves. For pool boiling on vertical surfaces the rising bubbles create turbulence that affects a larger area than the effect of bubbles forming on horizontal surfaces.

In the regime of nucleate boiling with forced convection the heat transfer remains independent of the bubble fraction in the fluid (quality of the fluid) only as long as there is sufficient liquid remaining to completely wet the hot surface. In cooling channels of rocket engines this condition is maintained only in the inlet portion. Shortly downstream of that zone there is a transition regime where nucleate boiling makes a transition to film boiling. The location of the transition zone is dependent on the cooling channel design and the operating conditions of the engine. This transition is a potential trouble spot and susceptible to burnout if the flame-side temperature of the chamber wall exceeds the melting point or softening point of the metal.

If one develops a formula for heat transfer to a liquid in a cooling channel, the bubble fraction or liquid quality must be carried along as an additional variable. The heat transfer to liquid hydrogen flowing through a cooling channel and partially evaporating along its path cannot be calculated using the conventional equations which assume an infinite supply of liquid. In any rocket propulsion system using a propellant stored in the liquid state, the existence of two-phase flow of the working fluid is of critical concern during start-up phase. It is generally required that the quality of the fluid at certain locations be predicted. But the behavior of single component, non-isothermal two-phase flow is not well understood. Fluid flow and heat transfer data under these conditions were lacking. An experimental program was undertaken to study forced convection, transient boiling heat transfer to hydrogen during cool-down of a metal test section [205]. The partial evaporation and heat transfer to a two-phase fluid are more difficult to express in mathematical equations than either nucleate boiling with sufficient liquid or complete evaporation in the film boiling mode [206].

NASA conducted very thorough investigations of heat transfer to liquid hydrogen. The test conditions covered liquid pressures between 208 and 481 kPa (2.05 and 4.75 atm), heat fluxes up to  $163 \text{ W cm}^{-2} = 1631760 \text{ W/m}^2 = 39 \text{ cal cm}^{-2} \text{ s}^{-1} = 390000 \text{ cal m}^{-2} \text{ s}^{-1}$  and temperature differences from 28 to 415 °C between the fluid and the wall [179]. Two different test-section geometries of 30-cm (1-ft) length were employed; one had a 15.9-mm (0.625-in.) outside diameter and 1.6-mm (0.065-in.) wall, and the other a 9.5-mm (0.375-in.) outside diameter and 0.8-mm (0.031-in.) wall. The wall temperature profile along the tube was radically different from that observed

in convective heat transfer with single-phase fluids. For the range of investigation, film boiling of the hydrogen and a resulting two-phase flow phenomenon occurred. Correlations were derived from heated tube data which apply to (1) film boiling of liquid hydrogen, (2) hydrogen at supercritical pressure just above and below critical temperature, (3) low temperature hydrogen (83–139 K) above the critical pressure [207, 208]. Heat transfer in the convective film boiling regime can be predicted by correlating the ratio of experimental to predicted Nusselt numbers with the Martinelli two-phase parameter. Experimental pressure drops varied greatly.

The question has been posed if under these conditions some of the parahydrogen may reconverted to orthohydrogen, an endothermic process. The rate of equilibrium adjustments in the absence of catalysts would be very slow. Iron would be catalytic, but gold would not. Since the para-ortho conversion is endothermic, it should help the heat transfer. A stainless steel tube would be expected to show a lower wall temperature than a gold-plated tube but the experimental data showed the gold-plated tube to give a lower wall temperature.

Heat transfer characteristics of cryogenic hydrogen flowing vertically upward in uniformly joule-heated straight tubes were assessed over the pressure range of 6.9–17.2 MPa (1000–2500 psia) [180]. The fluid appeared to exhibit gas-like behavior in this regime. Heat transfer data for the most part were predictable to  $\pm 20\%$  by the Nusselt-film correlation

$$\text{Nu}_f = C \text{Re}_f^p \text{Pr}_f^{0.4}$$

where  $C = 0.021$  and  $p = 0.8$ . A closer examination, however, of the data for each test section indicated that the Reynolds number exponent  $p$  can vary between 0.83 and 0.9 with the constant  $C$  changed correspondingly from 0.011 to 0.006. These correlations hold for heat fluxes up to  $1634 \text{ W/cm}^2$  ( $10 \text{ BTU in}^{-2} \text{ s}^{-1}$ ), wall-to-bulk temperature ratios to 11, mass flow rates to  $0.18 \text{ kg/s}$  ( $0.4 \text{ lb}_m/\text{s}$ ), film Reynolds number from  $10^5$  to  $4 \times 10^6$ , and inside tube diameters from 5.3 to 11.1 mm (0.21–0.438 in.).

Heat transfer studies with liquid hydrogen in the regime of film boiling with forced convection were conducted in a tube of stainless steel CRES-347 with an internal diameter of 14 and 0.89 mm wall thickness  $\text{s}^{-1}$  [209]. A length of 41 cm of the tube was heated in a furnace to different temperatures. The flow rate was up to  $12.7 \text{ kg/h}$  and the local maximum heat flux was  $12.5 \text{ W/cm}^2 = 3.0 \text{ cal cm}^{-2}$ . The transition from nucleate boiling to film boiling was evidenced by a steep increase of the wall temperature, similar to observations reported by other experimenters [210]. This group had flowed liquid hydrogen through a 30-cm (12-in.) electrically heated vertical Inconel tube with an outer diameter of 9.5 mm (0.375 in.) and a wall thickness of 0.8 mm (0.031 in.). The flow rate was  $13.6\text{--}86 \text{ g/s}$  and the pressure was  $206\text{--}482 \text{ kPa}$  ( $2\text{--}4.7 \text{ atm} = 30\text{--}70 \text{ psi}$ ). The temperature difference between the flowing fluid and the wall covered a range from 21 to  $550^\circ\text{C}$ . The maximum heat flux was  $130 \text{ W/cm}^2$  ( $31 \text{ cal cm}^{-2} \text{ s}^{-1}$ ). As illustrated in Figure 36, which shows data for a tube with an outside diameter of 0.95 cm (0.375 in.), it was noted that the wall temperature already reached its maximum value after only

1/10 of the length of the heated zone. The test conditions for the experiments shown in Figures 36 and 37 are listed in Table 23. The heat transfer coefficient, illustrated in Figure 37, at this point was at its minimum ( $3517 \text{ W cm}^{-2} \text{ K}^{-1} = 0.84 \text{ kcal m}^{-2} \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1} = 8.4 \times 10^{-5} \text{ kcal cm}^{-2} \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1} = 3024 \text{ kcal m}^{-2} \text{ h}^{-1} \text{ }^{\circ}\text{C}^{-1}$ ). Apparently at this point the transition to film boiling has already occurred, and the heat capacity and thermal conductivity of the cold, gaseous hydrogen is still quite low. Additional degrees of freedom of vibration and oscillation in the  $\text{H}_2$  molecule still need to be thawed. At the end of the tube the heat transfer coefficient again reaches values close to those at the inlet of the tube. Hydrogen leaving the tube consisted of 80% vapor.

**Figure 37:** Heat transfer coefficient during forced convection heat transfer to liquid hydrogen. (Adapted from [210] by permission from Springer Nature ©1961; permission conveyed through Copyright Clearance Center Inc.)

A general equation was developed for forced convective film boiling heat transfer in liquid hydrogen [211]. Forced flow heat transfers of liquid hydrogen through a vertical tube with a diameter of 6 mm and length of 100 mm were measured at pressures of 0.4, 0.7 and 1.1 MPa for various inlet temperatures and flow velocities [212]. The heat fluxes at the inception of boiling and the departure from nucleate boiling heat fluxes were higher for higher flow velocity and subcooling. The departures from nucleate boiling heat fluxes under subcooled conditions were lower for higher pressure. The effects of tube diameter and subcooling on the departure from nucleate boiling heat flux were investigated. A new correlation of saturated and subcooled departure from nucleate boiling heat flux was established based on these data and the data for 3-mm diameter tubes already reported earlier.

The heat transfer from the inner side of a vertically mounted heated tube with a length of 200 mm and a diameter of 6 mm to a forced flow of liquid hydrogen was

measured for wide ranges of flow rate and liquid temperature [213]. The non-boiling heat transfer coefficients agreed well with the Dittus-Boelter equation. The heat fluxes at departure from nucleate boiling were higher for higher flow velocities and greater subcooling. The effect of the tube length on the departure from nucleate boiling heat flux was clarified through comparison with previous data.

The knowledge of departure from nucleate boiling heat flux of liquid hydrogen is necessary for designing and cooling analysis of high critical temperature superconducting devices. Departure from nucleate boiling heat fluxes of liquid hydrogen were measured under saturated and subcooled conditions at absolute pressures of 400, 700, and 1100 kPa for various flow velocities [214]. Round heaters made from Pt-Co alloy, 200 mm long and 0.7 mm in diameter were arranged in the central axis of a flow channel made of fiber reinforced plastic with inner diameters of 8 and 12 mm. These test bodies were vertically mounted and liquid hydrogen flowed upward through the channel. Correlations of departure from nucleate boiling heat flux data under saturated and subcooled conditions with the experimental conditions were made.

In order to calculate the transient temperature rise of hydrogen when precooled hydrogen is flowing and unavoidably heated through the wall of transfer ducting at a refueling station, like the umbilical at the launch pad, the filling equipment was assumed to be a simple and straight pipe, and the heat balance based on the thermodynamics for hydrogen flowing in the pipeline was analyzed [215]. The internal surface temperature of the pipeline wall was needed to calculate the heat flux into hydrogen. A solution to obtain the temperature distribution in the pipeline wall when hydrogen with lower temperature than the pipeline flows unsteadily was proposed. Based on the proposed solution, the heat flux and the hydrogen temperature were calculated. The hydrogen temperatures predicted by this approach were compared with experimental data for the temperature rise of hydrogen heated through actual filling equipment, and good agreement was achieved.

The thermal behavior of flowing liquid hydrogen inside the cooling channels of the regenerative cooling system of a scramjet was modeled and measured at different channel sizes [216]. In order to find the optimum design parameters, a 3-D model of coolant flow in terms of the fuel real properties was developed and validated through experiments under different conditions of flow area, channel aspect ratio, fin thickness and coolant inlet temperature. For the given cases, the wall temperature was decreasing when the channel aspect ratio increased from 1 to 8, but there exists an optimal channel aspect ratio at a relatively large value. The optimal channel aspect ratio increased when the flow area became smaller. Decreasing fin thickness can significantly reduce the wall temperature without resulting in a large increase of pressure drop.

### 2.13.2 Heat Transfer Coefficient to Gaseous Hydrogen

In order to successfully design cooling channels for rocket engines, heat transfer data for both liquid *and* gaseous hydrogen must be known. The heat transfer to gaseous hydrogen was measured at Reynolds numbers from 3670 to 62200 and gas pressures from 274 to 689 kPa (2.7–6.8 atm) in a tube that was 31 cm long and had an diameter of 7.75 mm [217]. The ratio of wall temperature to gas temperature was varied from  $T_w : T_i = 1.17$ –2.47. The heat transfer to gaseous hydrogen can be represented by the following equation:

$$\text{Nu}_f = 0.023 \text{Re}_f^{0.8} \text{Pr}_f^{0.4}$$

where the subscript f designates the conditions along the film next to the wall. This work was later expanded to conditions of higher heat fluxes ( $2428 \text{ W/cm}^2 = 580 \text{ cal cm}^{-2} \text{ s}^{-1}$ ) and higher pressures (up to 9.3 MPa = 92 atm) [218]. Those results can be represented by a more complex equation:

$$\text{Nu} = \frac{hd}{\lambda_a} = 0.023 \left( \frac{\rho_a v d}{\eta_a} \right)^{0.8} \text{Pr}_a^{0.4} \left( \frac{T_w}{T_a} \right)^{-0.8}$$

where

$h$  = heat transfer coefficient,  $\text{kcal h}^{-1} \text{ cm}^{-2} \text{ }^\circ\text{C}^{-1}$

$d$  = internal tube diameter, cm

$\lambda_a$  = thermal conductivity of hydrogen at  $T = a$ ,  $\text{kcal h}^{-1} \text{ cm}^{-1} \text{ }^\circ\text{C}^{-1}$

$\rho_a$  = density of hydrogen at  $T = a$ ,  $\text{g/cm}^3$

$v$  = flow velocity, cm/s

$\eta_a$  = viscosity of hydrogen at  $T = a$ ,  $\text{g cm}^{-1} \text{ s}^{-1} = \text{Ps}$

$T_a$  = bulk temperature of hydrogen, K

For conditions in the boundary layer adjacent to the wall we can use a similar equation, where the subscript w indicates that this property must be taken at the wall temperature  $T_w$ :

$$\text{Nu} = \frac{hd}{\lambda_w} = 0.023 \left( \frac{\rho_w v d}{\eta_w} \right)^{0.8} \text{Pr}_w^{0.4}$$

These equations are valid for the following range of conditions:

|                                  |                         |
|----------------------------------|-------------------------|
| Reynolds number                  | 7800– $1.5 \times 10^6$ |
| Hydrogen gas initial temperature | 200–310 K               |
| Temperature ratio $T_w/T_a$      | 1.5–2.8                 |
| Wall temperature $T_w$           | 480–910 K               |
| Hydrogen bulk temperature $T_a$  | 310–406 K               |
| Hydrogen pressure                | 4.3–92 atm              |

Thermal conductivity and transport properties of hydrogen at extremely high temperatures, beyond the capabilities of experimentation, such as the temperatures expected

in some nuclear powered rocket engines from 300 to 10000 K can be calculated from theoretical considerations based on known thermodynamic properties [219]. In the upper end of this temperature regime molecular dihydrogen begins to dissociate. No experimental data exist for the transport properties of hydrogen in the dissociating region.

Transport properties were calculated for hydrogen in the pressure range from  $10^{-6}$  to  $10^2$  atm and at temperatures up to  $10^6$  K [220], also for heat transfer in rocket nozzles of gaseous-core nuclear rocket engines [221].

### 2.13.3 Heat Transfer to Hydrogen in the Supercritical State

#### 2.13.3.1 Heat Transfer to Hydrogen in the Near-critical State with Forced Convection

An experimental non-burnout study of heat transfer to hydrogen at near-critical temperatures flowing turbulently in resistance-heated straight and curved channels was made to evaluate the applicability of earlier heat transfer correlations to nozzle design [222]. Both straight and curved channels of circular cross-section were used, the latter being limited to simulating a single contour considered typical of a coolant passage in a rocket nozzle throat region. The fluid was heated asymmetrically by chemically milling the tube wall to reduce the metal thickness on one side. Inlet mass velocities ranged from 28.17 to 8618  $\text{kg m}^{-2} \text{s}^{-1}$  ( $62.2\text{--}19024 \text{ lb}_m \text{ m}^{-2} \text{s}^{-1} = 5.78\text{--}1768 \text{ lb}_m \text{ ft}^{-2} \text{s}^{-1}$ ). Local values of the pressure and bulk temperature ranged from 2.88 to 5.86 MPa (418–850 psia) and 28.2–161 K (50.9–290 °R) respectively, while local velocities ranging from 1.73 to 332 m/s (5.7–1095 ft/s) were obtained. The highest outer wall temperature measured was 1069 K (1925 °R), and the maximum inner wall temperature was computed as 610 K (1098 °R). The maximum local heat flux was 23.7  $\text{MW m}^{-2}$  (14.5  $\text{BTU in.}^{-2} \text{s}^{-1}$ ), and the highest value of the wall-to-bulk temperature ratio obtained was 18.5. Correlating equations were generated for the straight and curved tube geometries with fluid properties evaluated at the bulk temperature; however, analysis of the data indicated this simple correlation approach did not adequately express the data. A comparison of these equations with earlier correlations showed that the equation generated from straight tube tests was the most conservative and that generated from curved tube data was in general the most optimistic. Heat transfer to hydrogen flowing turbulently in straight asymmetrically heated tubes of circular cross-section was correlated by this equation, with fluid properties evaluated at the bulk temperature

$$\text{St}_b = 0.017 \text{Pr}_b^{0.96} \text{Re}_b^{-0.14} \left( \frac{T_w}{T_b} \right)^{-0.8}$$

Flow in curved tubes of circular cross-section was correlated by

$$\text{St}_b = 0.0346 \text{Pr}_b^{-0.3} \text{Re}_b^{-0.17} \left( \frac{T_w}{T_b} \right)^{-0.7}$$

A review of a method capable of including density fluctuations in the equations of turbulent transport indicated that the method may be used to predict heat transfer for the case of near-critical parahydrogen in turbulent upflow inside vertical tubes [223]. Wall temperatures, heat transfer coefficients and velocities obtained by coupling the equations of turbulent momentum and heat transfer with a perturbed equation of state showed good agreement with experiments for inlet reduced pressures of  $p/p_c = 1.28\text{--}5.83$ .

Four correlations which cover the ranges of liquid to gas transitions for turbulent flow convection of hydrogen were compared with computational fluid dynamics (CFD) analysis results over a range of expected design conditions for active cooling of hypersonic aircraft [224, 225]. The correlations compared here were those of Hess and Kunz, McCarthy and Wolf, Miller, Seader and Trebes, and Taylor. Analysis of hydrogen cooling in a typical cooling panel demonstrated how predicted design performance varies with the correlation used. The Taylor heat transfer coefficient correlation demonstrated the best overall agreement with the CFD results for constant heat flux over a wide range of pressure, temperature, mass flow, and heat load conditions. The McCarthy and Wolf correlation also agreed well with the CFD results. The CFD heat transfer coefficient results for a heat spike differed greatly from all four correlations. An acceptable heat transfer coefficient can be calculated at the heat spike location by ignoring the coefficient at the spike and averaging the coefficient before and after the spike.

### 2.13.3.2 Heat Transfer to Hydrogen in the Supercritical State with Forced Convection

Boiling point and critical point of hydrogen are so close together like no other gas used as a rocket propellant. The boiling point is at 20.27 K, and the critical temperature is at 33.3 K. The critical pressure is so low ( $1.297\text{ MPa} = 12.8\text{ atm}$ ), that it is easily exceeded with most rocket engine chamber pressures. In rocket engines operating at pressures above the critical pressure hydrogen can achieve supercritical conditions and enters the rocket engine or gas generator in the supercritical state [226–228]. In spite of this phase transition to supercritical conditions, hydrogen continues to be a good coolant for rocket engines over a wide range of temperatures and pressures.

Hydrogen heat-transfer data in the supercritical region has been compared with an analysis based on fully developed turbulent pipe flow with variable fluid properties [229]. The comparison indicated an additional variable property effect that was not included in the previous analysis. A new approach led to the correlation of the data over the full range of experimental conditions. These results indicated that the mechanism of supercritical heat transfer with hydrogen can be explained on the basis of variable fluid property effects without postulating a new mechanism for heat transfer, as was done in previous investigations. It was found that the pipe flow equation with fluid properties based on the film temperature can be made to correlate the data by correcting the calculated values with a simple function of wall to bulk kinematic

viscosity ratio. This method provided a rapid means for determining supercritical hydrogen heat transfer with an accuracy that was sufficient for most purposes.

Heat transfer to supercritical hydrogen is covered by mathematical equations which are quite different from the equations applicable to either gaseous or liquid hydrogen. Heat transfer by forced convection to cryogenic hydrogen at supercritical pressures has been studied experimentally, using a resistance-heated tubular test element [230, 231]. Test pressures were varied from 4.7 to 9.3 MPa (680–1344 psia) with fluid bulk temperatures at the test-section inlet ranging from 30 to 56 K (55–102°R). The maximum heat flux obtained was  $1307 \text{ W/cm}^2$  ( $8.0 \text{ BTU in.}^{-2} \text{ s}^{-1}$ ), while the maximum wall-to-bulk temperature ratio was 16.5. Heat transfer to hydrogen was found to be characterized by two mechanisms, each differing in its dependence on Reynolds number and the wall-to-bulk temperature ratio. Although mean residence times were only of the order of milliseconds, the data indicated that an appreciable fraction of the parahydrogen was converted to the ortho form, the degree of conversion increasing with wall temperature. In the neighborhood of the critical point the heat transfer coefficient of hydrogen passed through a minimum. Another minimum was observed at temperatures that were 28–40 K above the critical point temperature.

Heat transfer measurements reported in the early literature covered the range from 13 to 92 atm and 29 to 407 K. If one compares the heat transfer data for supercritical state hydrogen which were obtained experimentally under 14 different conditions, one will find that the measured numbers can be predicted with an accuracy of  $\pm 33\%$  by equations reported in the literature [232]. See also [207, 208, 233–236].

Turbulent flow of supercritical hydrogen through a uniformly heated circular tube for the range of  $4 \times 10^5 \leq \text{Re} \leq 3 \times 10^6$ ,  $5 \leq q_w \leq 10 \text{ MW/m}^2$ ,  $30 \leq T_{\text{in}} \leq 90 \text{ K}$ , and  $5 \leq P_{\text{in}} \leq 15 \text{ MPa}$  has been investigated using numerical methods [237]. The purpose was to validate a turbulence model and calculation method for the design of active cooling systems of hydrogen-fueled hypersonic aircraft, where the hydrogen fuel is used as coolant. The PHOENICS software package was used for the computations, which required special provision for evaluation of the thermophysical properties of the supercritical hydrogen, and a low Reynolds number form of the  $k$ - $\epsilon$  turbulence model. Pressure drop and heat transfer data were compared with experimental and existing correlations, and good agreement was demonstrated. For the pressure range considered, a “thermal spike” was observed and shown to be due to the secondary peak in specific heat, rather than the primary peak.

Heat transfer correlations for supercritical hydrogen and a study of the effects of uncertainties in hydrogen property data on the design of cooling channels showed that uncertainty due to property data alone can be as high as 10% [238]. Previous heated tube experiments with supercritical hydrogen were summarized, and data from a number of heated tube experiments were analyzed to evaluate conditions for which the available correlations are valid [239].

The transition from subcritical state to supercritical state severely influences the heat transfer of liquid hydrogen. In a numerical simulation study of the convective

heat transfer to supercritical hydrogen in a straight tube under high heat flux, the thermophysical properties and transport properties including the equation of state, specific heat capacity, viscosity, and thermal conductivity of hydrogen were evaluated first by comparison with the data from the National Institute of Standards and Technology (NIST) [240]. Then, the flow and heat transfer process was investigated using the Reynolds averaged Navier-Stokes (RANS) model, and the approach was validated by being able to successfully predict a behavior called “local heat transfer deterioration.” Further, the mechanism of heat transfer deterioration was analyzed based on detailed information of the flow field.

Wall temperature distribution and heat transfer coefficient during convective heat transfer to hydrogen flow are highly dependent on the heat flux profile imposed at the tube wall. The flow acceleration to a flat velocity profile contributes to the heat transfer deterioration [241].

The convective heat transfer to supercritical pressure hydrogen in a straight tube was investigated numerically by employing a computational model, which was simplified from experiments performed by Hendricks et al. [242]. During the simulation, the standard  $k-\epsilon$  model combining the enhanced wall treatment was used to formulate the turbulent viscosity, and the results validated the approach through successful prediction of wall temperature profile and bulk temperature variation.

### **2.13.3.3 Heat Transfer to Hydrogen in the Supercritical State without Forced Convection**

Both oxygen and hydrogen are commonly stored in cryogenic tanks under space zero- $g$  conditions, but not so much for rocket propulsion as for fuel cells for electricity generation. Therefore, the heat transfer to supercritical hydrogen under zero- $g$  conditions without external agitation poses a special problem that cannot be easily simulated on the ground [243]. Fuel cells with supercritical storage of fluids were used on GEMINI [244], APOLLO, and the Space Shuttle.

### **2.13.4 Practical Applications of Heat Transfer to Liquid Hydrogen**

Numerous rocket engines now use liquid hydrogen and heat transfer measurements on real-life operating rocket engines were made to validate the modeling that preceded their design. Nuclear thermal rockets with liquid hydrogen were tested briefly during the last century and posed unique heat transfer problems. One of the test series used the KIWI and ROVER reactors operated by the Los Alamos Scientific Laboratory [9, 11, 245]. Heat transfer experience gained during the operation of nuclear thermal rockets helped in the later design of large hydrogen-cooled chemical rockets.

In order to drive the liquid hydrogen pumps a peak power demand of 37 MW (50000 HP) was required that could not be drawn from the electric power grid in a remote area. Instead of storing electric power, the plant stored hot water and used it in heat exchangers to evaporate a portion of the liquid hydrogen to generate high

pressure hot hydrogen, which was used to drive a set of multi-stage turbines which in turn spun the liquid hydrogen pumps [246]. The expanded hydrogen was then dumped.

#### **2.13.4.1 Pressure Oscillations in Liquid Hydrogen**

At high heat fluxes to liquid or supercritical hydrogen at high stream velocities it is possible that the system will develop pressure oscillations which may propagate through the entire system, depending on the possible amplification by resonance in lines and cavities [247–249]. Such oscillations were disturbing enough in a stationary heat exchanger, but they would have been disastrous in a flight vehicle.

Thermal acoustic oscillations can occur whenever a long tube connects a region at cryogenic temperature with an ambient temperature, low pressure region where boiling occurs. Instrumentation lines and ports for fluid flow are examples where these conditions can exist. Thermal acoustic oscillations can occur without any net flow of fluid or any intended transfer of heat [250]. Thermal acoustic oscillations can lead to pressure surges in LH2 and slush hydrogen systems. Entry of LH2 into warmer instrument or discharge lines causes local vaporization and a pressure increase, which forces the LH2 and GH2 gas back to the bulk LH2, where cooling causes a reverse surge. Such back and forth oscillations can result in an increased heat input to the bulk LH2. This is related to geysering if it occurs in vertical tubes.

#### **2.13.4.2 Radiation Heating of Hydrogen**

In addition to conventional heat transfer from hot walls to liquid hydrogen flowing through an operating nuclear fission reactor (KIWI-A or NERVA type) the moving fluid may absorb neutrons and will pick up additional energy converted to heat [251, 252]. Unshielded nuclear radiation from an operating nuclear reactor absorbed into liquid hydrogen (which is a good neutron moderator) may result in nuclear heating of the unused propellant in the hydrogen storage tank adjacent to the reactor [253], potentially leading to premature cavitation in the inducer section of the hydrogen pump [254].

#### **2.13.4.3 Heat Transfer to Uninsulated Tanks**

In order to predict vaporization losses from an uninsulated tank, the heat transfer coefficients to an uninsulated copper plate at 20 K were investigated [255]. Data were taken over a range of air velocities, normal to the surface, of 0–9.3 m/s (0–21 miles/h), varying absolute humidity of air, and ambient air temperatures of 264–338 K (16–150 °F). A theoretical analysis, description of experimental apparatus and procedure, experimental results, discussion, and conclusions were presented. The results can be summarized as follows: **(1)** low ambient temperatures and absolute humidity inhibit and sometimes prevent frost accumulation on the test surface; **(2)** steady state frost thickness increases with air velocity and absolute humidity; **(3)** heat transfer coefficients exhibit a minimum point at all air velocities when plotted against absolute humidity; **(4)** the only theoretical analysis made was for the surface

covered with a liquid air film. No correlation between theory and experimental data was found to exist.

#### 2.13.4.4 Heat Transfer to Liquid Hydrogen in Nuclear Thermal Rockets

The understanding of heat transfer from a nuclear fission reactor to flowing liquid and gaseous hydrogen as measured during the NERVA, ROVER, and PHOEBUS experiments is also useful for the design of cooling channels in chemical rockets. The predicted pressure and temperatures at the exit of the cooling passages were compared with the measured values of EP-IV nuclear tests and were in good agreement with each other [256]. Incremental values of coolant temperatures and pressures, coolant passage wall temperatures, and heat flux to the coolant were calculated. A constant gas coefficient  $C$  of 0.026 yielded predicted values for coolant exit pressure and temperature that were in good agreement with measured values. Maximum wall temperature and heat flux were in good agreement with those calculated using the conventional varying coefficient.

Application of variable property heat transfer and friction equations to rocket nozzle coolant passages and comparison with nuclear rocket test results provided another set of data points [257]. Calculated local gas-side wall temperatures were compared with wall temperatures indicated by melting of selected braze alloys from NERVA nuclear tests. Several different heat transfer correlations were used to predict temperatures on the hot-gas side and wall temperatures.

### 2.14 Critical Constants of Hydrogen

The critical constants used for correlating density data near the critical point are listed in Table 24.

**Table 24:** Critical constants of hydrogen.

| Constant                                    | References |
|---------------------------------------------|------------|
| $\rho_c$                                    |            |
| 0.01559 $\pm$ 0.00005 g mol/cm <sup>3</sup> | [102]      |
| 0.01527 $\pm$ 2% g mol/cm <sup>3</sup>      | [258]      |
| 0.02909 g/cm <sup>3</sup>                   | [61]       |
| $T_c$                                       |            |
| 32.976 $\pm$ 0.015 K                        | [102]      |
| 32.984 $\pm$ 0.020 K                        | [258]      |
| 33.19 K                                     | [61]       |
| $P_c$                                       |            |
| 12.759 $\pm$ 0.028 atm                      | [102]      |
| 12.770 $\pm$ 0.04 atm                       | [258]      |
| 1292 kPa = 12.751 atm                       | [61]       |

## 2.15 Equation of State of Liquid Hydrogen

It was noticed very early that the equation of state of liquid hydrogen deviates substantially from the equations of state for other cryogenic liquids [105]. If the  $pV$  isotherms are known for a specific temperature and pressure condition, the compressibility can be calculated by differentiating the data. Detailed PVT tables are contained in a number of publications, including those by [61, 259]. See also [74, 260, 261].

A very simple, but approximate equation of state, while not adequate for computation of thermal properties, may, if valid over a wide range, be useful as a concise representation of the mechanical properties of a fluid like liquid hydrogen [262]. In particular, it would provide a continuous reference with which to compare experimental PVT data for purposes of smoothing, accomplished by examining differences.

The PVT surface presented by NBS covers both gaseous and liquid regions from the triple point to the critical point [93, 263]. Another equation of state gives qualitatively correct behavior in the critical region, i.e., “scaling-law” behavior [264].

A reasonably condensed table of PVT saturation properties and transport data of parahydrogen is offered in Table 2.2 on page 8 of [70].

Compressibility measurements and thermodynamic properties data for parahydrogen were extended to higher temperatures and pressures [265]. Results of an experimental program were presented in the form of pressure, volume, and temperature data in the temperature range 23–300 K at pressures up to 80 MPa (800 bar). Second and third virial coefficients can be calculated by two groups of polynomial equations, one for temperatures below 100 K and another for temperatures above 100 K. Tables for virial coefficients to be used in the standard equation of state are available in [41].

A truncated virial equation was based on the current parahydrogen equation of Younglove 1982 and is limited to low-density vapor states [266]. The density uncertainty for this equation is the same as that of Younglove 1982, but it has fewer terms making it suitable for engineering calculations.

A Benedict-type PVT equation of state was derived from high-pressure sound velocity data together with previously reported volume and ultrasonic velocity data at low pressures and temperatures, that is valid for fluid hydrogen up to the maximum pressures and temperatures with an average deviation of 1% from the new and previously published experimental data [115].

New fundamental equations of state for parahydrogen, normal hydrogen, and orthohydrogen were developed to replace existing, outdated property models [267]. To accurately predict thermophysical properties near the critical region and in liquid states, the quantum law of corresponding states was applied to improve the normal hydrogen and orthohydrogen formulations in the absence of available experimental data. All three equations of state have the same maximum pressure of 2000 MPa and an upper temperature limit of 1000 K.

## 2.16 Solubility, Miscibility, Mixtures, Solutions of Hydrogen

### 2.16.1 Solubility of Hydrogen in Other Fuels

Theoretically it should be possible to improve the performance of other rocket fuels by dissolving hydrogen in the liquid fuels. Unfortunately, the solubility of dihydrogen in other fuels is very poor.

### 2.16.2 Pressurant Gas Solubility in Liquid Hydrogen

There are numerous studies published on the phase diagrams of hydrogen/helium mixtures at very high pressures [268–272]. Hydrogen/helium mixtures would not be very practical as rocket propellants. At normal hydrogen storage pressures, the solubility of helium in liquid hydrogen is only very small. Helium is used as a pressurant in liquid hydrogen tanks to bring the tank pressure up to a point that it will prevent cavitation in the inlet section of propellant pumps. At the normal boiling point of helium, hydrogen has already frozen to a solid. There may even be a miscibility gap in a certain region. Experiments on phase behavior in hydrogen-helium mixtures have been carried out at pressures up to 9.3 kilobars, at temperatures from 260 to 1000 K [273]. Two distinct fluid phases were shown to exist at supercritical temperatures and high pressures. Both the trend of the experimental results and an analysis based on the van der Waals theory of mixtures suggest that this fluid-fluid phase separation persists at temperatures and pressures beyond the range of these experiments, perhaps even to the limits of stability of the molecular phases. The results confirmed earlier predictions concerning the form of the hydrogen-helium phase diagram in the region of pressure-induced solidification of the molecular phases at supercritical temperatures. This phase diagram may have implications for planetary interiors of giant gas planets.

The main reason for the study of hydrogen/helium mixtures at very high pressures is the indication that such mixtures may exist at very high pressures surrounding the cores of the giant gaseous planets, Jupiter and Saturn [274]. Models of Jupiter and Saturn postulate a central rock core surrounded by a fluid mixture of hydrogen and helium. These models suggest that the mixture is undergoing phase separation in Saturn but not Jupiter. State-of-the-art total energy calculations of the enthalpy of mixing for ordered alloys of hydrogen and helium confirm that at least partial phase separation has occurred in Saturn and predict that this process has also begun in Jupiter.

Equilibrium properties of hydrogen-helium mixtures under conditions similar to the interior of giant gas planets for densities between 0.19 and 0.66 g/cm<sup>3</sup> and temperatures from 500 to 8000 K were studied by means of first-principles density functional molecular dynamics simulations [275].

At very high pressures, hydrogen is more likely to turn into a metallic phase than helium with free mobility of electrons among the nuclei. At even higher pressures, it will fuse into helium as in the sun and in hydrogen atomic bombs. A good source of energy for rocket propulsion, but difficult to control.

Additional studies of the phase relationships of hydrogen/helium mixtures at high pressures in a pressure range from 15 to 75 kbar and at temperatures from 110 up to 360 K determined three-phase line solid-fluid-fluid and showed that the divergency of these lines persists up to the highest pressures and that the fluid-fluid equilibrium region extends to higher temperatures and higher pressures [276, 277].

Helium is the only pressurant for liquid hydrogen fuel tanks other than warm hydrogen gas. Precise composition measurements of this mixture are necessary for predictive models for propellant pressurization and transfer. Pressure-Volume-Temperature composition (PVT-x) measurements of cryogenic helium-hydrogen mixtures taken with a Rubotherm IsoSORP 2000 dual-sinker magnetic suspension microbalance that had been retrofitted for cryogenic service, measured the solubility of helium in liquid hydrogen. This system has been validated by direct comparison to previously published experimental data and extended the range of helium-hydrogen density measurements. The range of possible measurements extended from 10 to 288 K for pressures up to 275 bar.

Although NASA has used helium gas to pressurize liquid hydrogen propellant tanks for decades, little is known about the interactions between helium gas and liquid hydrogen. Traditionally, helium gas is injected into the liquid hydrogen propellant tank to maintain constant tank pressure. This method was used on the Space Shuttle and will continue to be used on the Space Launch System that is under development by NASA.

Tests using the Multipurpose Hydrogen Test Bed at NASA MSFC to evaluate the effects of helium pressurant on the performance of a spray bar thermodynamic vent system with an ambient heat leak of about 70–80 W and tank fill levels of 90, 50, and 25% successfully controlled the tank pressure within a  $\pm 3.45$  kPa ( $\pm 0.5$  psi) band with various helium concentration levels in the ullage [278]. Relative to pressure control with an “all hydrogen” ullage, the helium presence resulted in 10–30% longer pressure reduction durations, depending on the fill level. The time to opening the vent depended on activating the mixer in the tank to prevent stratification. Ullage stratification was present, and the ullage pressure was successfully controlled without the mixer operating. It was evident that the spray bar configuration, which extended almost the entire length of the tank, enabled significant thermal energy removal from the ullage even without the mixer operating.

Liquid hydrogen saturated with helium at atmospheric pressure contains 0.17 mol-% helium. The rate of self-pressurization of liquid hydrogen tanks is different for tanks containing pure hydrogen and tanks containing helium-saturated hydrogen [279]. The model compared the tank performance for the traditional model that assumes no helium pressurant dissolves into the liquid hydrogen propellant to an updated model that accounts for dissolved helium pressurant. Traditional NASA models have been unable to account for this dissolved helium due to a lack of fundamental property information. The self-pressurization model was run assuming

that the liquid propellant was pure liquid hydrogen and assuming helium dissolved into the liquid utilizing the new helium-hydrogen EOS. The analysis showed that having dissolved helium in the propellant does not have a significant effect on the tank pressurization rate for typical tank conditions (20.4 K and 206 kPa =  $-423^{\circ}\text{F}$  and 30 psia). The model predicted a  $0.2^{\circ}\text{F}$  difference in the propellant temperature over the course of a 10-h mission when accounting for dissolved helium pressurant. Calculations showed that dissolved helium slightly decreases the rate at which the propellant temperature rises [280, 281].

## 2.17 Thermodynamic Properties of Hydrogen

The publication by Woolley, Scott, and Brickwede [61] contains voluminous tables of the thermodynamic properties of hydrogen. Additional data on thermodynamic properties of hydrogen can be found in the publications listed in Table 25 which cannot all be reproduced here because they contain too much detailed information.

**Table 25:** Sources for data on thermodynamic properties of hydrogen.

| Properties                              | Author                     | Year | References |
|-----------------------------------------|----------------------------|------|------------|
| Thermodynamic properties                | Altman                     | 1956 | [282]      |
| Parahydrogen                            | Goodwin et al.             | 1964 | [74]       |
| Thermodynamic and transport properties  | Hilsenrath et al.          | 1960 | [73]       |
| Thermochemical tables                   | JANAF                      |      | [283]      |
| Thermodynamic properties                | Krascella                  | 1963 | [284]      |
| Thermodynamic properties from 1 to 22 K | Mullins, Ziegler, and Kirk | 1963 | [285]      |

Changes of temperature during isentropic expansion of normal hydrogen in nozzles were computed assuming equilibrium composition for chamber pressures from 0.96 kPa to 10 MPa, pressure ratios from 1 to 3000, and chamber temperatures from 600 to 5000 K [290]. Computed parameters included nozzle-exit pressure and temperature, enthalpy, molecular weight, isentropic exponent, specific heat at constant pressure, absolute viscosity, thermal conductivity, Mach number, specific impulse in vacuum, ratio of nozzle-exit to throat areas, thrust coefficient, specific impulse, equilibrium gas composition, characteristic velocity, and entropy. Additional properties of gaseous normal hydrogen, orthohydrogen, and parahydrogen were calculated for several pressures at temperatures below 600 K.

The report by [41] contains very detailed tables and graphs of the thermodynamic properties of hydrogen in various physical states as a function of temperature and pressure.

With the advances in computing power of computers, much of the work on thermodynamic properties of hydrogen is now not experimental, but computational, as indicated by relatively recent reviews of the status of thermodynamic properties of hydrogen [291, 292].

Many applications expose hydrogen to temperatures even higher than those encountered in chemical rockets. Thermodynamic properties of 20.4 K-equilibrium hydrogen for pressures between 6.9 kPa and 20.7 MPa (1 and 3000 psia) and temperatures between 14 and 2777 K (between 25 and 5000 °R) were tabulated, including temperature-entropy, enthalpy-entropy, pressure-enthalpy, temperature-enthalpy, and temperature-density diagrams [293]. At high temperatures a study of the gas properties must consider the effects of dissociation and non-ideal gas behavior.

Compressibility measurements and thermodynamic properties data for parahydrogen were extended to higher temperatures and pressures [265]. Tables contained thermodynamic properties on isobars to 100 MPa (1000 bar) including density, internal energy, enthalpy, entropy, specific heats at constant volume and constant pressure, velocity of sound, and surface derivatives.

The PVT properties of compressed normal hydrogen (75% orthohydrogen and 25% parahydrogen) up to 100 MPa and its equation of state (EOS) derived from the measurement data of the Burnett method, along with a correlation of viscosity and thermal conductivity for compressed hydrogen have been summarized [95, 294].

## **2.17.1 Heat Capacity of Hydrogen**

### **2.17.1.1 Heat Capacity of Solid and Liquid Hydrogen**

The heat capacity at constant pressure of liquid parahydrogen at the triple point is  $c_p = 6.36 \text{ J g}^{-1} \text{ K}^{-1}$  and at the boiling point it is  $9.66 \text{ J g}^{-1} \text{ K}^{-1}$ . For comparison, the heat capacity of gaseous parahydrogen at the triple point is  $10.52 \text{ J g}^{-1} \text{ K}^{-1}$  and at the boiling point it is  $12.15 \text{ J g}^{-1} \text{ K}^{-1}$ . Heat capacity data of solid and liquid normal and parahydrogen are listed in Tables 26 and 27.

Table 26: Molar heat capacity  $C_p$  and heat capacity  $c_p$  of solid and liquid hydrogen.

| Phase           | Temperature |         | Molar heat capacity                 |                                        | Heat capacity                     |                                      | Data source                        | References |  |  |

### 2.17.1.2 Heat Capacity of Solid Hydrogen

Heat capacity data for solid parahydrogen are listed in Table 28. Specific heat, thermal conductivity, and thermal diffusivity of solid hydrogen are highly sensitive to actual ortho-para composition. A composite picture for the heat capacity of solid hydrogen containing varying amounts of ortho and parahydrogen is shown in Figure 38. This graph is similar to Figure 38 in [41].

The report by Roder et al. 1973 [70] also contains data for the heat capacity of compressed solid hydrogen under pressures of up to 400 atm. Heat capacity of solid hydrogen decreased with increasing pressure.

The lattice heat capacity of solid hydrogen was measured at zero pressure and at three constant volumes [297, 298], Table 26. The measurements extended from 2 K to the triple point for the zero pressure data, from 2 K to the melting temperature at  $22.56 \text{ cm}^3/\text{mol}$ , and from 4 to 20 K at  $19.83$  and  $18.73 \text{ cm}^3/\text{mol}$ . The isothermal compressibility at 16.35 K at the melting pressure is essentially the same as at 4.2 K at the same pressure. The thermal expansion coefficient at 8.31 MPa (82 atm) appears to have a maximum at about 12 K. At zero pressure the thermal expansion coefficient is approximately proportional to the temperature. For two of the samples there was an anomalous contribution to the heat capacity at low temperatures because the sam-

Note:  $C_S$  is the heat capacity along the saturation line

Data source: [70, 297, 298]

**Figure 38:** Heat capacity of solid hydrogen containing varying amounts of ortho and parahydrogen. (Reproduced and modified from [70].)

ples contained some orthohydrogen. This contribution was subtracted and caused a small additional uncertainty where it was appreciable. The heat of melting at the triple point was  $118 \pm 1$  J/mol. The volume change on melting was estimated to be 4% or  $0.1 \text{ cm}^3/\text{mol}$ . The experimental values of the lattice heat capacity were plotted on large scale graphs in the form of  $C/T^3$  vs.  $T^2$ . These graphs were extrapolated to  $T^2 = 0$ . Other authors [299] had reported heat capacities of solid hydrogen that varied by as much as 14% at 3 K from the more recent data by Ahlers.

Measurements have been made in the temperature range 0.5–5 K of the specific heats of pure solid  $\text{H}_2$ , pure solid  $\text{D}_2$ , and four solid mixtures of  $\text{H}_2$  and  $\text{D}_2$  with  $\text{D}_2$  fractions between 15 and 95%, all of which systems had low concentrations of molecules in the rotational state  $J = 1$  typical for orthohydrogen [300]. The observed specific heats could be described as the sum of three terms: a lattice specific heat, a Schottky term with a maximum at about 1.3 K for solid  $\text{H}_2$  and a second anomalous term occurring at temperatures below about 0.8 K and, by extrapolation, having its maximum below 0.5 K.

### 2.17.1.3 Heat Capacity of Liquid Hydrogen

Values for the  $C_p$ ,  $C_v$ , and  $C_s$  of liquid parahydrogen are shown in Figure 39. Values for the graph were taken from the thermodynamic tables of Roder et al. which in turn were based on the measurements of  $C_v$  and  $C_s$  by Younglove and Diller [296]. Equally detailed and accurate tables of values for saturated liquid and compressed liquid states for parahydrogen from the freezing liquid line to 2700 K (5000 °R) for pressures to 69 MPa (10000 psia) were given [289]. Additional experimental measurements of hydrogen properties at pressures greater than 340 atm have been published [301].

As mentioned above, the differences in specific heats for different orthohydrogen-parahydrogen compositions in the liquid state are very small [84, 88]. For additional heat capacity data see [302]. For additional heat capacity data  $C_v$  at constant volume and high pressure, see [296, 303].

### 2.17.1.4 Heat Capacity of Gaseous Hydrogen

The heat capacity of gaseous hydrogen between 298 and 6000 K can be calculated from a Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $\tau$  is the temperature in kelvin divided by 1000. The constants A through H are listed in Table 29 for three different temperature ranges.

**Figure 39:** Heat capacity of liquid parahydrogen. (Reproduced and modified from [70].)

**Table 29:** Constants for Shomate equations for gaseous hydrogen

| Constant | Value      |            |            |
|----------|------------|------------|------------|
|          | 298–1000   | 1000–2500  | 2500–6000  |
| A        | 33.066178  | 18.563083  | 43.413560  |
| B        | −11.363417 | 12.257357  | −4.293079  |
| C        | 11.432816  | −2.859786  | 1.272428   |
| D        | −2.772874  | 0.268238   | −0.096876  |
| E        | −0.158558  | 1.977990   | −20.533862 |
| F        | −9.980797  | −1.147438  | −38.515158 |
| G        | 172.707974 | 156.288133 | 162.081354 |
| H        | 0.0        | 0.0        | 0.0        |

$H^\circ$  = standard enthalpy (kJ/mol)

Data source: [83]

Isentropic expansion of hydrogen gas is a key step in the liquefaction process and data for the isentropic heat capacity have been tabulated [304]. The difference in heat capacity of ortho, para and normal (equilibrium) hydrogen changes over a wide range of temperatures, as shown in Figure 40.

**Figure 40:** Reduced specific heat differences between equilibrium, normal, ortho and parahydrogen in the ideal gas state. (Reproduced and modified from [62]).

### 2.17.2 Enthalpy of Formation of Hydrogen

The reference state for enthalpy is zero for the ideal gas at zero kelvin absolute temperature. The reference state heat of formation of liquid parahydrogen at the triple point is  $-308.8\text{ J/g}$  and at the boiling point it is  $-256.3\text{ J/g}$ , this is more negative than the reference state heat of formation of normal hydrogen which is  $+218.3\text{ J/g}$  at the triple point and  $+270.9\text{ J/g}$  at the boiling point. The reference state enthalpy of parahydrogen gas at the triple point is  $140.3\text{ J/g}$  and at the boiling point it is  $189.3\text{ J/g}$ , compared to normal hydrogen gas which is  $667.4\text{ J/g}$  at the triple point and  $716.5\text{ J/g}$  at the boiling point.

By definition, the standard enthalpy of formation of hydrogen gas under standard conditions at  $298\text{ K}$  is zero ( $\Delta H_{298\text{ gas}} = 0.00\text{ kJ/mol}$ ). The enthalpy of formation of liquid parahydrogen, at the normal boiling point is  $-7.895\text{ kJ/mol} = -1.887\text{ kcal/mol}$ . The NASA CEC Thermo.inp list uses a heat of formation for LH2 of  $-9012\text{ J/mol}$  [89].

The differential enthalpy of formation of gaseous hydrogen in the temperature range 298–6000 K can be calculated from the equation

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{t} + F - H$$

where  $H$  is the enthalpy of formation in J/mol and  $\tau$  is the temperature in kelvin divided by 1000. The constants were already shown in Table 29 above. This equation is shown in the NIST Chemistry WebBook [83].

The heat of conversion of hydrogen from normal hydrogen to parahydrogen is listed in Table 30. See also Figure A1.2 on page A4 of NASA Hydrogen Systems Safety Standard [305].

**Table 30:** Heat of conversion from normal to parahydrogen.

| Temperature<br>K | Heat of conversion |          |
|------------------|--------------------|----------|
|                  | J/mol              | cal/mol  |
| 10               | 527.139            | 253.9865 |

Data source: [61]

### 2.17.3 Heat of Combustion of Hydrogen

The heat of combustion of hydrogen per unit mass is higher than that of any other material, but hydrogen has a relatively low heat of combustion per unit volume. Thus, the combustion of a given volume of hydrogen will release less energy than the same volume of either natural gas or gasoline. Heat of combustion (lower)  $(\Delta H)_{\text{Comb}}$ , (gaseous at 298 K = 25 °C) 241.8 kJ/mol = 57.79 kcal/mol = 28.6696 kcal/g.

Heat of combustion (upper)  $(\Delta H)_{\text{Comb.}}$  (gaseous at 298 K = 25 °C) 285.8 kJ/mol = 68.31 kcal/mol = 33.89 kcal/g. Except for the different polarity sign, this number is identical with the standard enthalpy of formation of liquid water.

#### 2.17.4 Heat of Fusion of Solid Hydrogen

The heat of fusion of solid parahydrogen at the triple point was reported as  $118 \pm 1$  J/mol ( $28.2 \pm 0.2$  cal/mol) [297, 298]. The heat of fusion of parahydrogen at 13.95 K is  $117.5 \pm 0.6$  J/mol =  $28.08 \pm 0.15$  cal/mol [84]. This is the average of two measurements taken between 13.4 and 14.7 K. Data for the heat of fusion of solid hydrogen along the melting line over a wide range of temperatures and pressures are listed in Table 31.

**Table 31:** Parahydrogen properties along the melting line

| Temperature<br>K | Pressure<br>atm | Molar vol-<br>ume of the<br>liquid<br>cm <sup>3</sup> /mol | Molar vol-<br>ume of the<br>solid<br>cm <sup>3</sup> /mol | Enthalpy of<br>the liquid<br>J/mol | Heat of<br>fusion<br>J/mol | Enthalpy of<br>the solid,<br>J/mol |
|------------------|-----------------|------------------------------------------------------------|-----------------------------------------------------------|------------------------------------|----------------------------|------------------------------------|

Data source: [70]

The latent heat of fusion of solid  $p$ -H<sub>2</sub> at constant pressure was measured at various temperatures and at pressures up to 34.25 MPa (338 atm) [100]. The data are well reproduced by the linear equation:

$$\Delta H_{\text{fus}} = 0.044149P + 28.041$$

where  $\Delta H_{\text{fus}}$  is the latent heat of fusion in cal/mol and  $P$  is the pressure in atm. Other sources give this equation as

$$\Delta H_{\text{fus}} = 0.044149P + 28.02693164$$

A generally accepted value for the heat of fusion of solid hydrogen at the triple point is 117.277 J/mol.

### 2.17.5 Heat of Vaporization of Liquid Hydrogen

The heat of evaporation decreases with increasing temperature and approaches zero as the temperature nears the critical point. In the following, heat of vaporization data from various sources dating back to the past century are assembled and some discrepancies in the data were noted. Some of the differences may be due to varying degrees of ortho→para conversion (Table 32).

The heat of vaporization between the triple point and the normal boiling point can be expressed by the equation

$$\Delta H = 219.7 - 0.27 (T - 16.6)^2,$$

where  $\Delta H$  is the heat of vaporization in cal/mol and  $T$  is the temperature in kelvin [306].

Raw, uncorrected calorimetric data for the heat of vaporization of parahydrogen are listed in Table 33. These early data do not match very well with data reported by other investigators which were mostly derived from vapor pressure measurements. The hydrogen was equilibrated at 20.4 K over a catalyst for several hours before the measurements were made, and thus should have contained only a very small amount of orthohydrogen.

The heat of vaporization as a function of temperature can be computed from the Clapeyron equation and a set of vapor pressure data. The heat of vaporization of parahydrogen derived from PVT data is listed in Table 34 from Reference [102]. These data were updated by the same author 10 years later.

**Table 32:** Heat of vaporization of liquid hydrogen.

| Ortho-para isomer | Temperature | Heat of vaporization ( $\Delta H$ ) <sub>evap.</sub> |                |       |       | Authors              | References |

Data source: [70]

The data in Table 34 were compared to older literature data and the deviations were less than 0.2% below the boiling point but approached 6–8% near the critical point. A more recent set of data gave the heat of vaporization of normal and parahydrogen as summarized in Table 35. The heat of vaporization of parahydrogen at the triple point is 448.2 J/g and at the normal boiling point it is 445.5 J/g. The heat of vaporization of normal hydrogen at the triple point is not much different from that of parahydrogen, it is 449.1 J/g at the triple point and 445.6 J/g at the normal boiling point. The heat of vaporization of parahydrogen as a function of temperature is illustrated in Figure 41.

Data for latent heat of vaporization of parahydrogen from [102] and latent heat of vaporization of normal hydrogen were compiled from numbers calculated by Roder et al. (1963) from the Clausius-Clapeyron equation and were compared and the resulting differences in heat of vaporization between the two modifications of hydrogen are illustrated in Figure 42 [30, 308].

### 2.17.6 Entropy of Hydrogen

Entropy data for liquid and gaseous hydrogen are listed in Table 36. The entropy of gaseous hydrogen in the temperature range 298–6000 K can be calculated from the polynomial equation

$$S^\circ = A \ln(\tau) + B\tau + \frac{C\tau^2}{2} + \frac{D\tau^3}{3} - E/(2\tau^2) + G$$

where  $S^\circ$  is the standard entropy in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $\tau$  is the absolute temperature in kelvin divided by 1000. The constants were already shown in Table 29 above. This equation is shown in the NIST Chemistry WebBook [83].

**Table 35:** Enthalpy of vaporization of normal and parahydrogen.

| Temperature<br>K | Latent heat of vaporization<br>Normal hydrogen |       |       |       | Parahydrogen |       |       |       | Difference<br>cal/mol |
|------------------|------------------------------------------------|-------|-------|-------|--------------|-------|-------|-------|-----------------------|
|                  | cal/mol                                        | J/mol | cal/g | J/g   | cal/mol      | J/mol | cal/g | J/g   |                       |

**Figure 42:** Difference in latent heat of vaporization of normal and parahydrogen. (Reproduced and modified from [62].)

Additional data on enthalpy and entropy of parahydrogen are summarized in [309]. The report by McCarty, Hord, and Roder 1981 [41] contains very detailed tables and graphs of the entropy of hydrogen in various physical states as a function of temperature and pressure.

The temperature-entropy diagram for parahydrogen three-phase region at and near the triple point was presented on the graphical coordinates of temperature and entropy [310]. Isobars from 10 mm Hg to 340 atmospheres, temperatures from 11 to 230 K and specific volumes covering the range of from 10.5 to 15000 cm<sup>3</sup>/g were included.

## 2.18 Molecular Structure of Solid Hydrogen

Typical crystal structures for solid parahydrogen, are hexagonal close packed structure with  $a = 3.75\text{--}3.761\text{ \AA}$ ,  $c = 6.105\text{--}6.14\text{ \AA}$ , and the  $c/a$  ratio = 1.623 – 1.633. There were some discrepancies in the literature about the exact crystal structure of solid hydrogen and its isotopes [311].

## 2.19 Optical Properties of Hydrogen

### 2.19.1 Infrared Spectra of Hydrogen

Infrared analysis of contaminants in liquid hydrogen would be difficult because hydrogen is a poor solvent and all contaminants would be suspended as particulate solids. While the Raman spectra of ortho and parahydrogen are sufficiently different to allow analysis of the parahydrogen content in gas mixtures, the IR spectra are not.

Induced infrared absorption of hydrogen is caused by the asymmetric distortion of the absorbing molecule by intermolecular forces. In crystalline hydrogen asymmetric distortion can be produced both by the random orientations of the freely rotating molecules and by the vibrational motion of the crystal lattice. The experimental results indicated that the first type of distortion occurs for quadrupole interactions, and that both types are operative for overlap interactions [312, 313]. IR spectra of high-pressure gaseous, liquid, and solid hydrogen show an increasing sharpness of the absorption bands as shown in Figure 43. In solid parahydrogen the lines become very sharp, and the double transition, Q1(0) + S0(0), shows a complex structure.

The induced infrared fundamental absorption band of liquid and solid hydrogen was investigated over a range of para-H<sub>2</sub> concentrations from 25 to 100% with a prism spectrometer and, in part, with a grating spectrometer at a resolution of  $\sim 0.2\text{ cm}^{-1}$  [314]. The spectrum of the solid showed **(a)** comparatively sharp lines due to quadrupole interaction, **(b)** broad bands interpreted as combination tones of the molecular frequencies with the lattice frequencies (phonon spectra), and **(c)**

**Figure 43:** Infrared absorption of hydrogen induced by intermolecular forces. (Reprinted and modified from [312], with permission from ©1955 American Physical Society; permission conveyed through SciPris)

weak double transitions. In solid parahydrogen the lines became very sharp and the double transition showed a complex structure.

A rich spectrum composed of hundreds of sharp features has been observed in the fundamental Q-branch of normal solid  $H_2$  using laser spectroscopy [315]. These features were interpreted as splitting of ortho- $H_2$  pairs.

### 2.19.2 Raman Spectra of Hydrogen

Raman spectra of ortho and parahydrogen differ sufficiently such that this method can be used to analyze the parahydrogen content of gas samples [316, 317].

### 2.19.3 Index of Refraction of Hydrogen

The refractive index of a non-polar fluid depends on the wavelength of the incident light, the density of the fluid and, to a lesser extent, the temperature. The dependence of the refractive index on temperature is usually small enough to be neglected.

The index of refraction of liquid hydrogen was determined at five wavelengths for saturated liquid at 745.52 mm Hg pressure corresponding to a temperature of 20.316 K [318]. The determination was made by measuring critical angles. The experiment was very similar to that of Johns and Wilhelm [319]; however, because of the way in which the optical cell was constructed, the measurements gave the ratio of the refractive indices of saturated liquid and vapor, whereas the refractive indices by Johns and Wilhelm were referenced to vacuum. Augustin obtained the refractive indices of the liquid from the above ratios by using estimated values of the refractive index of the vapor.

The refractive indices of liquid oxygen, nitrogen, and hydrogen at temperatures ranging from the normal boiling point to the normal freezing point of the liquefied gases were determined by means of a Wollaston cell for the wavelengths 6939 Å, 5461 Å, and 4358 Å. The values obtained at the normal boiling point for  $\lambda = 5461$  Å were: oxygen, 1.2242; nitrogen, 1.1990; hydrogen, 1.1120 [319]. Results from measurements on normal hydrogen from the triple point to the normal boiling point at the wavelengths 4358, 5461, and 6939 Å are shown in Table 37. The specific refractions, as calculated using the densities of Kamerlingh Onnes and Crommelin, showed no dependence on temperature or density. These have later been recalculated using modern density data.

Belonogov and Gorbunkov [320, 321] determined the refractive index of saturated liquid parahydrogen from about the normal boiling point (nbp) to 30.5 K and at the wavelengths, 4360, 5460, and 5790 Å. They also determined the refractive index of saturated liquid normal hydrogen over the same temperature range but at 5460 Å only. Their temperature range meets that of the other investigators at about the nbp but does not overlap it. As of 1965, these were the only data for the refractive index of parahydrogen or the para-normal difference.

**Table 37:** Index of refraction for liquid hydrogen.

| Temperature<br>K | °C     | Wavelength, nm | Index of refraction |
|------------------|--------|----------------|---------------------|
| 19.8             | -253.3 | 435.8          | 1.1142              |
| 17.2             | -255.9 | 435.8          | 1.1199              |
| 13.9             | -259.2 | 435.8          | 1.2440              |
| 19.8             | -253.3 | 546.1          | 1.1121              |
| 17.4             | -255.7 | 546.1          | 1.1169              |
| 13.9             | -259.2 | 546.1          | 1.1221              |
| 19.8             | -253.3 | 693.9          | 1.1108              |
| 19.5             | -253.6 | 693.9          | 1.1121              |

Data source: [319]

The published experimental values of the refractive index of liquid hydrogen from four different sources have been correlated by calculating and comparing the values of the Lorentz-Lorenz ratio as a function of wavelength [322]. The data from Augustin were judged to be the most accurate ones (0.7% deviation) and those by Belonogov and Gorbunkov the least accurate ones (–1.8% deviation). Because of the scatter found by this analysis, it was proposed that more accurate values can be calculated from available data of other types, namely, the dielectric constants and the optical dispersion determined for the gas at STP. Formulas for this calculation were given and the results are shown in Figure 44.

The two curves in Figure 44 above show the extremes given by various computational methods for saturated liquid hydrogen. The lower one is for the triple point density. The upper one is for the density at which  $p$  and  $r$  are maximum. This is near to

**Figure 44:** Specific refraction of liquid hydrogen as a function of wavelength. (Reproduced and modified from [322].)

the critical density. With further decrease of density,  $p$  and  $r$  decrease again towards the lower curve. See also [323].

The refractive index of gaseous and liquid hydrogen has been measured by an interferometric method at temperatures between 15 and 298.15 K and at pressures up to 23.3 MPa (230 atm) [324, 325]. The measurements have been analyzed in terms of the density and temperature dependence of the Lorentz-Lorenz function,

$$L-L \equiv \frac{n_{\lambda}^2 - 1}{n_{\lambda}^2 + 2} \rho^{-1}$$

where  $n_{\lambda}$  is the refractive index at  $\lambda = 5462 \text{ \AA}$  and  $\rho$  is the fluid density in  $\text{g/cm}^3$ . The precision and reproducibility of L-L is better than 0.05% in most cases. L-L for gaseous parahydrogen first increased with increasing density to a maximum and then decreased to values below the low-density limit. L-L is also slightly temperature dependent; the low-density limit increased with increasing temperature;

**Figure 45:** Index of refraction of saturated liquid parahydrogen. (Reproduced and modified from [41].)

the maximum on the L-L isotherms decreased with increasing temperature. L-L for saturated liquid parahydrogen decreased with increasing density by about 0.1% at temperatures between 15 and 32 K. The difference in L-L for normal and parahydrogen is consistent with previous theoretical and experimental estimates of the molecular polarizability difference. The temperature dependence of the refractive index of parahydrogen is illustrated in Figure 45. Data for refractive index of fluid hydrogen at high pressures between 1 and 9 GPa and temperatures between 293 and 490 K were measured in a diamond anvil [115].

## 2.20 Electrical and Magnetic Properties of Hydrogen

### 2.20.1 Electrical Conductivity of Hydrogen

Data from the organic chemicals and petroleum industries indicated that flowing fluids with conductivities in the  $10^{-11}$ – $10^{-15}$  mho/cm range could present electrostatic potential build-up and discharge hazards, particularly in situations of large volume storage and high flow rates. Liquid hydrogen, because of the possible explosion hazard, was of particular concern [326]. When trying to measure the electric conductivity of liquid hydrogen, the boiling of the liquid hydrogen introduced a large noise signal which made measurements very difficult [327]. Flowing non-conductive liquids can cause build-up of electrostatic charges. Such potentials are generated by flow of insulating fluids in the  $10^{-11}$ – $10^{-15}$   $\Omega^{-1} \text{ cm}^{-1}$  range. It was established that the conductivity of liquid hydrogen was below this range but the actual conductivity was not measured.

Measurements of the electrical conductivity of LH2 gave a typical resistivity of about  $10^{19}$   $\Omega \text{ cm}$  at 25 V and seemed to be a linear function of applied voltage. It was suggested that this current can be explained in terms of charge carriers formed by background radiation. Thus, the current carrying capacity is small and more or less independent of the imposed voltage. Some investigators suggested that electric charge build-up in flowing high-purity LH2 is not a great concern [328].

### 2.20.2 Dielectric Constant of Hydrogen

Early data on dielectric constant of gaseous hydrogen were inconsistent and one critical investigator stated “In a majority of, cases, values of the dielectric constant measured at radio frequencies do not appear to be of sufficient accuracy to provide useful information for reference purposes.” Some investigators derived a dielectric constant from index of refraction measurements [329].

The dielectric constant of liquid hydrogen is a linear function of temperature as shown in Figure 46 and represented by equation

$$\epsilon = 1.296 - 0.00345T$$

where  $\epsilon$  is the dielectric constant (dimensionless) and  $T$  is the temperature in kelvin.

**Figure 46:** Dielectric constant of liquid hydrogen as a function of temperature. (Chart created by Schmidt 2018, based on data from [144].)

Polarizabilities, calculated from measurements of the dielectric constant, were reported for solid parahydrogen along the melting line between 18 and 320 atm (14.4–22.2 K) [90, 91]. The data for density, polarizability, and dielectric constant of solid hydrogen under pressure are summarized in Table 38.

**Table 38:** Polarizability and dielectric constant of liquid parahydrogen as a function of density and temperature or pressure of the compressed fluid.

| Density<br>g/cm <sup>3</sup> | Polarizability<br>cm <sup>3</sup> /g | Dielectric constant<br>ε | Temperature<br>K | Pressure<br>atm |

Data source: [90,91]

The slight decrease in polarizability with pressure on the melting line is much less than the decrease for the liquid over the same pressure range. Since the dielectric constant is proportional to density, a plot of  $\epsilon$  vs.  $T$  is very similar to a density-temperature phase diagram. For parahydrogen, liquid and solid boundaries are shown in Figure 47.

**Figure 47:** Dielectric constant of saturated solid and liquid parahydrogen as a function of temperature. (Reproduced and modified from [70].)

The measured dielectric constant of solid and liquid parahydrogen as a function of temperature is illustrated in Figure 48. The dielectric constant for fluid parahydrogen may be calculated from the equation

$$\frac{\epsilon - 1}{\epsilon + 2} = A\rho + B\rho^2 + C\rho^3$$

where  $\epsilon$  is the dielectric constant (dimensionless),  $\rho$  is the density in  $\text{g/cm}^3$  and  $A$ ,  $B$ , and  $C$  are constants ( $A = 0.99575$ ,  $B = -0.09069$ ,  $C = 1.1227$ ). This equation is valid from the freezing liquid line to 3000 K and 100 MPa, as illustrated in Figure 49. The dielectric constant of liquid hydrogen is 1.252 at the triple point, 1.229 at the boiling point and 1.00025 at the critical point. The dielectric constant of solid hydrogen is 1.285 at the triple point. The dielectric constant of gaseous hydrogen is 1.00038.

The dielectric coefficient is determined from the ratio of the capacitance of a three-terminal, flat plate capacitor when it is filled with liquid hydrogen to that when the capacitor is in vacuum at the same temperature. Precision dielectric coefficient measurements of subcooled equilibrium liquid hydrogen in the temperature range from 15 to 23 K and under pressures up to 1 MPa were performed using a three-terminal flat plate

**Figure 48:** Dielectric constant of parahydrogen vapor at the saturated vapor-liquid boundary as a function of temperature. (Reproduced and modified from [70].)

**Figure 49:** Dielectric constant of parahydrogen at high pressures. (Reproduced and modified from [41].)

capacitor and a single-frequency, ultra-precision capacitance bridge, Figure 50 [97]. The results were combined with previously published data to express the dielectric coefficient in the form of the Clausius-Mossotti relation with a new correlation which covers both liquid and gaseous hydrogen and is only a function of the density. Capacitance/dielectric coefficient measurements are useful for measuring fluid hydrogen liquid level, mass gauging, and void fraction in two phase flow. A new equation of state gives the density as a function of pressure and temperature for the subcooled liquid phase.

The density of liquid  $p$ -H<sub>2</sub> over the density range 0.066–0.080 g/cm<sup>3</sup> (4.1–5.9 lb/cu.ft.) can be determined by measurement of the dielectric constant ( $\epsilon$ ) by use of the equation:

$$\rho = 0.29503 + 17.936(\epsilon - 1)$$

where  $\rho$  is the density in lb/cu.ft. and  $\epsilon$  is the dielectric constant (dimensionless), or, better, in metric units

$$\rho = 4.72591 + 287.304(\epsilon - 1)$$

where  $\rho$  is the density in mg/cm<sup>3</sup> and  $\epsilon$  is the dielectric constant (dimensionless).

### 3 Chemical Properties and Analysis of Hydrogen

#### 3.1 Reactions of Hydrogen with Inorganic Compounds

In order to achieve energy release from hydrogen it has to be combusted with a suitable oxidizer. The most commonly used oxidizer for this purpose is oxygen. Hydrogen will begin to react with oxygen only if preheated to above the ignition temperatures or in the presence of catalysts which significantly lower the activation energy of this reaction and allow ignition to take place at room temperature. The most frequently used catalysts for this purpose contain platinum. For instance, two centuries ago, prior to the invention of safety matches and flint striker sparkers, it was common practice for smokers to carry or have on their desk a small zinc/sulfuric acid hydrogen generator and the hydrogen was ignited in air on a platinum sponge (Döbereiner lighter), such that the smokers could satisfy their craving for nicotine.

If oxygen gas and hydrogen gas are pre-mixed, they could be stored for a long time without reaction. It would not be very safe to store such a mixture because once ignited (on purpose or accidentally) it would burn rapidly with explosive force (“Knallgas” in German, literally translated as “bang gas” in English).

The use of hydrogen as a fuel in rocket engines with oxygen or fluorine as the oxidizer will be discussed in future *Encyclopedia of Rocket Propellant* sets on Bipropellant Combinations.

Fluorine is a stronger oxidizer than oxygen and will ignite most other fuels hypergolically, but in mixture with hydrogen at room temperature and at lower temperatures near that of liquid fluorine it will not always ignite, which is surprising. The reaction of fluorine gas with hydrogen gas is often delayed and inhibited by an uncontrollable and unpredictable impediment and is difficult to explain [330–332]. Some experimenters have been able to mix fluorine gas with hydrogen gas at room temperature without ignition [333]; however, once ignition takes place, the mixture will burn or detonate with the same explosive hazard as the better-known oxygen/hydrogen mixtures. Metal surfaces may act as catalysts and facilitate ignition of  $F_2/H_2$  at room temperature.  $F_2/H_2$  combinations as rocket propellants will be discussed in more detail in a future *Encyclopedia of Rocket Propellant* set on Bipropellant Combinations. This reaction, also with deuterium instead of hydrogen, is of interest as a propellant for chemical lasers.

The Material Safety Data Sheet (MSDS) lists lithium metal as being incompatible with hydrogen. Is it possible that the reaction between lithium metal and hydrogen forming lithium hydride starts on its own and it is exothermic?

##### 3.1.1 Kinetics of $O_2/H_2$ Reactions

The reaction of hydrogen with oxygen is a fundamental reaction and has been thoroughly investigated both as a flame and as a flameless or catalyzed reaction. At one

point or another, be it on Earth or in the depth of space where water-bringing comets once formed, this reaction has formed all the water that now fills the oceans of our planet. In the upper atmosphere of Earth, water vapor is photolyzed by sunlight and the recombination reaction allows some water to form, but the rest of the hydrogen is carried away with the solar wind. One can design a rocket without exact knowledge of hydrogen oxidation kinetics, but kinetics will control certain aspects of hydrogen combustion, such as combustion instabilities, that can have a pronounced effect on the safe operation of a rocket engine. Accidental ignition of hydrogen leaks and the rates of propagation of hydrogen flames are determined by kinetics.

This section on kinetics of hydrogen oxidation is only a random sampling of the literature on this subject and does not claim to be a complete overview of this subject. There are better and more complete literature sources available to consult for the academic researcher in need of kinetic data for combustion reactions.

A detailed kinetic mechanism was developed to simulate the combustion of  $O_2/H_2$  mixtures over a wide range of temperatures, pressures, and equivalence ratios [334]. A series of experimental data taken from various sources with temperatures ranging from 298 to 2700 K, pressures from 0.05 to 87 atm, and equivalence ratios from 0.2 to 6 was compared to the predictions of the kinetic model. Ignition delay times, flame speeds, and species composition were simulated only with varying success. A sensitivity analysis was carried out to determine which reactions were dominating the  $O_2/H_2$  system at particular conditions of pressure, temperature, and fuel/oxygen/diluent ratios. Overall, good agreement was observed between the model and the wide range of experiments simulated.

A revised chemical kinetic mechanism model of hydrogen combustion was validated against a wide range of experimental conditions, including those found in shock tubes, flow reactors, and laminar pre-mixed flames [335]. Excellent agreement of the model predictions with experimental measurements demonstrated that the mechanism was comprehensive and had good predictive capabilities for different experimental systems, particularly high-pressure laminar flame speed and shock tube ignition results. The reaction  $H + OH + M$  was found to be primarily significant only to laminar flame speed propagation predictions at high pressure. All experimental hydrogen flame speed observations can be adequately fitted using any of the several transport coefficient estimates presently available in the literature for the  $O_2/H_2$  system simply by adjusting the rate parameters for this reaction within their present uncertainties.

An analysis of the performance of an updated hydrogen combustion mechanism paid particular attention to different channels of reaction between H atoms and  $HO_2$  radicals, to pressure dependence of the recombination of  $HO_2$  radicals, and to the anomalous rate constant of reaction between OH and  $HO_2$  radicals [336]. The contemporary choice of the reaction rate constants is presented with the emphasis on their uncertainties. The model predicted ignition, oxidation, flame burning velocities and flame structure of oxygen/hydrogen/inert mixtures. The modeling range covered ignition experiments from 950 to 2700 K and from subatmospheric pressures up to 87 atm,

hydrogen oxidation in a flow reactor at temperatures around 900 K from 0.3 to 15.7 atm, flame burning velocities in oxygen/hydrogen/inert mixtures from 0.35 up to 4 atm and hydrogen flame structures at 1 and 10 atm. A comparison of the model predictions and experimental results revealed the remaining limitations in terms of the range of applicability of this detailed mechanism.

An updated  $O_2/H_2$  reaction mechanism incorporated reaction rate determinations in shock tubes [337]. These experiments used UV and IR laser absorption to monitor species time-histories and have resulted in improved high-temperature rate constants for the following reactions:

The updated mechanism also took advantage of the results of other rate coefficient studies, and incorporated the most recent thermochemical data for  $\bullet OH$  and  $HO_2^\bullet$ . The mechanism was tested (and its performance compared to that of other  $O_2/H_2$  mechanisms) against recently reported  $\bullet OH$  and  $H_2O$  concentration time-histories in various  $O_2/H_2$  systems, such as  $H_2$  oxidation,  $H_2O_2$  decomposition, and shock-heated  $H_2O/O_2$  mixtures. The mechanism was validated against a wide range of standard  $O_2/H_2$  kinetic targets, including ignition delay times, flow reactor species time-histories, laminar flame speeds, and burner-stabilized flame structures.

An updated  $O_2/H_2$  kinetic model based on that of Li et al. [335] was tested against a wide range of combustion targets, incorporating improvements in rate constant treatment and resolving discrepancies between experimental data and predictions using published kinetic models in dilute, high-pressure flames [338]. Attempts were made to identify major remaining sources of uncertainties, in both the reaction rate parameters and the assumptions of the kinetic model, affecting predictions of relevant combustion behavior. With respect to model parameters, uncertainties in the temperature and pressure dependence of rate constants for  $HO_2$  formation and consumption reactions substantially affect predictive capabilities at high-pressure, low-temperature conditions. With respect to model assumptions, calculations were performed to investigate several reactions/processes that had not received much attention previously. Results from *ab initio* calculations and modeling studies imply that inclusion of

in the kinetic model might be warranted, though further studies may be necessary to ascertain its role in combustion modeling. In addition, it appears that characterization

of non-linear bath-gas mixture rule behavior for

in multi-component bath gases might be necessary to predict high-pressure flame speeds within ~15%. The updated model was tested against all of the previous validation targets as well as new targets from a number of other studies. Predictions using this model adequately reproduced various targets and substantially improved agreements with high-pressure flame speed and shock tube speciation measurements.

Nine chemical reaction models for equilibrium schemes and six chemical models for non-equilibrium ones for the reaction of oxygen and hydrogen were studied, considering different conditions found in real liquid oxygen/liquid hydrogen rocket engines [339]. Comparisons between two eight-species models have shown that the most complex is also the best one. Besides, it was also verified that the most complex model has been the fastest among six-species and eight-species models. Both combustion temperature and thermochemical and transport properties depend only on the chemical species considered by the used model. Analyses have shown that mass generation rates are very dependent on third body reaction equations and forward reaction constants.

Termolecular reactions  $\text{H} + \text{O}_2 + \text{R}$  may significantly affect kinetic pathways under common combustion situations and require careful analysis, since, if included in contemporary kinetic mechanisms, these reactions will affect global reactivity and calculated burning velocities of laminar pre-mixed flames [340]. In view of their impact, a detailed kinetic scheme for hydrogen combustion was revisited to elucidate how to counterbalance enhanced chain termination caused by chemical termolecular reactions in an attempt to maintain or improve model performance. Experimental and theoretical kinetic studies of hydrogen reactions were compared. In the new mechanism, four new reactions were introduced and three rate constants were updated. These changes, however, significantly reduced calculated burning velocities of air +  $\text{H}_2$  flames as compared to experimental data and earlier model predictions with the major impact from chemically termolecular reactions. It was then found that implementation of a new theoretical transport properties database significantly improved the performance of the updated kinetic model. The new kinetic mechanism for hydrogen combustion, which included updated kinetics and new transport properties was found to be in good agreement with the consistent dataset of the burning velocity measurements for hydrogen flames obtained using the heat flux method at atmospheric pressure for which the accuracy of the previous model was not satisfactory.

The reaction rate of

in the low-pressure limit was determined in the temperature range of 1450–2000 K, with argon, nitrogen, and carbon dioxide as the third-body collision partners, by mea-

asuring the  $\bullet\text{OH}$  time-history after the induction time during lean oxidation of hydrogen [341]. A strong transition in the spectrum of  $\bullet\text{OH}$  was used as the probing wavelength for the diagnostics. Calibration measurements were performed prior to the experiments to estimate the effects of pressure shift and collision broadening on the absorption coefficient of  $\bullet\text{OH}$  for each of the gas species, which enabled a reduction in the uncertainty in the absorption cross-section of  $\bullet\text{OH}$ . Aided by the calibrated and improved  $\bullet\text{OH}$  diagnostics, the reaction rate constants were determined at high temperatures, with low scatter, and tight uncertainty bounds. The measured rate constants agreed with the extrapolation of previous investigations at lower temperatures. Combined rate constant expressions were proposed, which are valid over the temperature range of 1000–2000 K

### 3.2 Combustion of Hydrogen

Basically this entire section is devoted to the combustion of hydrogen, dealing mostly with academic and safety studies. Actual applications of hydrogen combusting rocket and ramjet engines will be presented in a future *Encyclopedia of Rocket Propellant* set on Bipropellant Combinations.

#### 3.2.1 Burning Velocity of Air/Hydrogen Flames

This section on flame speed (i.e., burning velocity) of hydrogen flames is closely related to Section 7.2 on Fire Hazards of Hydrogen and Section 5.5 on the design of flare stacks for the disposal of surplus hydrogen gas.

##### 3.2.1.1 Burning Velocity of Air/Hydrogen Flames at Sea-Level Pressure

The high burning velocity of hydrogen, approximately 6–7 times faster than that of hydrocarbon fuels, indicates its high explosive potential and explains the difficulty of preventing, confining or arresting hydrogen flames and explosions.

Burning velocities of air/hydrogen mixtures were measured by the Bunsen burner method [342]. A modified angle technique applied to the dark outer edge of the shadow cone was used in calculating the burning velocities. An attempt was made to correlate the experimental results with approximate diffusion and thermal theories of flame propagation. It was found that diffusion theory predicted a maximum in burning velocity at a much leaner hydrogen composition than was observed experimentally, whereas thermal theory produced the opposite situation by predicting a maximum at a richer composition (29 vs. 42 vs. 55 vol.-%  $\text{H}_2$ ).

The laminar burning velocity is defined as the velocity of unburned gas with given composition, pressure, and temperature that flows normal to the stationary flame surface. The measurement of laminar burning velocity must be performed to

obtain a physical constant free of the effects of geometry, fluid flow, and external heat sources or heat sinks [343]. The flame speed, a function of the frame of reference, is a combination of the burning velocity and the translational velocity of the bulk flow. Combustion behavior for scenarios in which hydrogen, released in the open, forms a flammable mixture, may be compared to the characteristics of laminar burning behavior. The hazard associated with laminar burning is the propagation of a high-temperature flames throughout the region where a flammable mixture persists. Without confinement of the reaction products, high flame velocities do not occur, nor is there any overpressure. Burning velocities reported for sensitive air/hydrogen mixtures under ambient conditions range between 1 and 3.5 m/s, with peak velocities observed for mixtures fuel-rich than stoichiometry, approximately 40 vol.-% (Figure 51).

**Figure 51:** Burning velocity of hydrogen in air. (Reproduced and modified from [343].)

The burning velocity of air/hydrogen mixtures and mixtures of methane, ethane, propane, *n*-butane, acetylene, ethylene, propylene, and *n*-butylene with air as a function of the fuel:air ratio has been measured in an apparatus capable of measuring the burning velocity of gas-air mixtures with an accuracy of about 5% [344].

Conical air/hydrogen flames have been stabilized on a 10.3-mm diameter water-cooled nozzle burner designed so as to minimize the flashback tendency and to maintain laminar flow at very high rates [345]. Measurements of the cone half-angle,  $\theta$ , by schlieren optical techniques and the unburned gas velocity,  $V$ , by particle-tracking techniques have been used to determine burning velocity from the equation  $S_u = V \sin \theta$ . A burning velocity of 296 cm/s was obtained for a 50% hydrogen-air flame, whereas others reported the burning velocity to be approximately 250 cm/s. This discrepancy was attributed to errors in the earlier measurements caused by the use of averaging methods with very small burners. There was good agreement between the present experimental value of burning velocity and the value computed for a 50% air/hydrogen flame by others.

A method for the prediction of one-dimensional laminar flame propagation, using the time-dependent equations, used a very simple flame, that of hydrazine decomposition, to demonstrate the usefulness of the method [346]. This procedure was then used for an oxygen/hydrogen/nitrogen flame which can be characterized by reaction mechanisms for which an abundant number of adequate chemical kinetic data exists. As well-documented experimental studies of this flame showed, a critical comparison of predicted and measured flame characteristics can be used to explain some details of the reaction more accurately than previously possible. The results of two investigations were presented: the first concerned the effect of excluding some of the possible reactions from a very full reaction scheme on the prediction of flame speed; the second investigation resulted in recommendations for reaction rates of some of the reactions, for which there was still some uncertainty in the existing data.

A mathematical solution of the conservation equations governing a freely propagating laminar flat flame has been performed for the oxygen-hydrogen-nitrogen system [347, 348]. A reaction mechanism with rate constants from recent reviews was given which reproduced within the limits of experimental errors flame velocities in oxygen/hydrogen and oxygen/hydrogen/nitrogen mixtures between 10 and 1000 cm/s.

The difference in modes of flame propagation that occurs between the upward lean limit at 4%  $H_2$  and the downward lean limit near 8%  $H_2$  is quite anomalous for any flammable gas. Upward propagation from a convectively rising flame kernel involves propagation into a velocity gradient induced by buoyancy forces and at a slow but finite propagation velocity, the flame is blown out by its own buoyancy-induced flow [349]. Data for the laminar burning velocity of air/hydrogen mixtures obtained from such a nearly adiabatic burner system are shown in Figure 52.

**Figure 52:** Burning velocity of hydrogen in air. (Reproduced and modified from [349].)

The solid lines represent measured burner data and the dashed lines represent theoretical estimates but are not real data. There is no combustion beyond these limits. The arrows at lean limits and rich limits indicate the direction of flame propagation. This figure contains a vertical scale change, from linear to logarithmic at velocities above 50 cm/s. It also contains a horizontal scale discontinuity (scale compression) at concentrations above 10% H<sub>2</sub>.

The burning velocities of hydrogen-air and hydrogen-air-steam mixtures as a function of the temperature and composition of the unburned gases have been measured by laser-Doppler anemometry and schlieren photography using a constant velocity nozzle burner [350, 351]. A two-cyclone in-series particle generator was designed to provide a suitable particle seeding rate for the laser-Doppler anemometer. The overall method was checked by comparing measurements for air/methane mixtures with published data, which were obtained from both hot wire measurements in spherical propagating flames and double-ignition measurements in a closed vessel. Excellent agreement was observed. Burning velocities of air/hydrogen mixtures measured at room temperature agreed well with those reported by others. New data have been obtained for the burning velocity as a function of unburned gas temperature. The addition of steam to an air/hydrogen mixture noticeably decreased the burning velocity. A correlation equation has been derived from the observed

burning velocities covering a hydrogen concentration range of 18–65 vol.-%, a steam concentration range of 0–15 vol.-%, and a temperature range of 296–523 K (23–250 °C).

Laminar and turbulent burning velocities of air/hydrogen mixtures have been determined in a 17-L vessel using the double-kernel technique for a range of hydrogen concentrations between 9 and 70% by volume [352]. Over the range of mixtures investigated, simple empirical correlations were derived that predicted laminar burning velocities that were in good agreement with those measured. A turbulent-burning-velocity correlation that included the flame-generated turbulence produced burning velocities in good agreement with the values measured experimentally. The data and correlations for the hydrogen burning velocity were used in models to predict hydrogen combustion behavior in enclosures containing hydrogen-air-diluent mixtures and in combustion systems that employ hydrogen as the fuel.

The burning behavior of air/hydrogen fast deflagrations and detonations was investigated in an explosion tube for pre-mixed flames, partially diluted with additives [353]. The flames were accelerated after ignition by means of a cascade of obstacles. The structure of the reaction zone was determined by means of planar laser-induced predissociation fluorescence, whereas the shape of both flame front and shockwaves was investigated by means of color-schlieren technique in the unblocked tube section. On the basis of the obtained experimental results, quantitative criteria for the onset of slow and fast deflagrations as well as shock-induced combustion phenomena (spin/marginal detonations, planar cellular detonations) were obtained. The maximum pressure spikes were observed at the end of the tube for fast deflagrations.

Laminar burning velocities of air/hydrogen flames were measured at ambient temperatures for variable equivalence ratios [354]. The apparatus consisted of a 250-mm long cylindrical stainless steel explosion bomb enclosed at one end with a stainless steel plug which housed an internal stirrer to allow mixing. The other end was sealed with a 120-mm diameter round quartz window. Optical access for filming flame propagation was afforded via two diametrically opposed quartz windows in both sides. Flame speeds were determined within the bomb using a high-speed Schlieren photographic technique. This method is an accurate way to determine the flame speed and the burning velocities were then derived using a CHEMKIN computer model to provide the expansion ratio. The design of the test facility ensured the flame is laminar, which resulted in a spherical flame which was not affected by buoyancy.

Very rich near-limiting air/hydrogen flames were studied in a constant volume bomb equipped with a pressure sensor and a schlieren system for optical registration of the flame front movement [355]. The mixtures contained 70 and 75 vol.-% of hydrogen, the rest being air. The measurements were conducted at pressures from 101 to 404 kPa (1–4 atm) for the 70 vol.-% H<sub>2</sub> + air mixture and from 71 to 142 kPa (0.7–1.4 atm) for the 75 vol.-% H<sub>2</sub> + air mixture. Two methods for determination of the laminar burning velocity were used: from the temporal evolution of the flame front movement and

from the pressure records. These methods were compared and discussed in terms of accuracy and implicit assumptions behind them. Markstein lengths were calculated and compared with literature data by using different extrapolation models. The critical radius is an important parameter for extraction of the burning velocity and Markstein length. Experimental data were compared to three models for hydrogen combustion.

The flame burning velocities of unconfined air/hydrogen gas explosions depend on the cloud size and the distance from the initiating source, related to turbulence generated by the propagating flame front [356]. The molecular absorption bands in the flame front are exposed to continuously increasing radiation intensity of water emission bands from the interior of the reaction product fire ball. The air/hydrogen flame propagation in 1-m diameter balloons was observed by high-speed video techniques including time resolved spectroscopy in the UV-Vis-NIR spectral range with a time resolution up to 3000 spectra/s. Ignition, flame head velocity, flame contours, reacting species and temperatures were evaluated. Flame front velocities were found to be between 16 and 25 m/s.

Outwardly propagating spherical hydrogen/air flames were examined theoretically and experimentally with respect to flame propagation speed and the onset of instabilities which develop due to thermal expansion and non-equal diffusivities [357]. Instabilities increase the surface area of the spherical flame, and hence the flame propagation speed. The theory applied here accounted for both hydrodynamic and diffusive thermal effects, incorporating temperature-dependent transport coefficients. Experiments were performed in a spherical combustion chamber over a wide range of equivalence ratios (0.6–2.0), initial temperatures (298–423 K), and initial pressures (1 atm–15 bar). The evolution of the flame propagation speed as a function of flame radius was compared to predictions from theory and showed good agreement. The wrinkling of air/hydrogen flames was examined under increased pressure and temperature for various equivalence ratios. Critical flame radii, defined as the point of transition to cellular flames, were extracted from high-speed schlieren flame imaging. Overall, the critical radius was found to decrease with increasing pressure. Experimental flame radii, as expected, were underpredicted by the theoretical findings. Experimental data were fitted to an empirical formula.

Flame flashback is a major challenge in pre-mixed flame studies and the design of flare stacks. The prediction of the minimum flow velocity to prevent boundary layer flashback is of high technical interest. An analytic approach to predicting boundary layer flashback limits for channel and tube burners developed a model which was based on an experimentally observed flashback mechanism and consisted of a local and global analysis [358]. Based on a local analysis, the flow velocity at flashback initiation was obtained depending on flame angle and local turbulent burning velocity. The local turbulent burning velocity was calculated in accordance with a predictive model for boundary layer flashback limits of duct-confined flames. The flame angle of the stable flame near flashback conditions can be obtained by various methods. An

approach based on global mass conservation was applied and was validated using Mie-scattering images from a channel burner test rig at ambient conditions. The predicted flashback limits were compared to experimental results and to literature data from preheated tube burner experiments.

### 3.2.1.2 Burning Velocity of Air/Hydrogen Flames at Reduced Pressures

It would be desirable to operate jet engines with hydrogen at high altitudes. During the ignition phase, flames have to propagate at low ambient pressure. Measurements of burning velocity at pressures other than atmospheric are difficult. This is especially true for reduced pressures. The experimental difficulties are reflected in large discrepancies in the literature data of the few workers who have studied combustion of air/hydrogen mixtures at low pressures. One ancient source [359] reported nearly constant burning velocity at total pressures from 1 to 4 atmospheres. Another source [360] gave burning velocity values of 164 cm/s at 0.393 atm and 140 cm/s at 1 atm for a mixture with  $\phi = 4.78$ . The burning velocity of a mixture with  $\phi = 3.58$  increased when the pressure was raised from 0.25 to 1.0 atm [361]. The same trend was shown between  $\phi$  of 1.10 and 1.90 [362, 363]. The data of Manton and Milliken 1956 are probably most correct, because the spherical bomb technique is not subject to some of the important sources of error that affect results obtained by other methods. The cause of the discrepancy between these two data sources is not known. Figure 53 shows burning velocities from two sources plotted logarithmically against pressure for four rich equivalence ratios. The data from Fine 1956 were obtained by a Bunsen

**Figure 53:** Effect of pressure on burning velocity of air/hydrogen flames. (Reproduced and modified from [343].)

burner total area method, and care was taken to avoid quenching effects from too-small burner tube.

Stability limits for laminar and turbulent air/hydrogen burner flames were measured as a function of pressure, burner diameter and composition [363, 364]. The average pressure exponent of the critical boundary velocity gradient for turbulent flashback was 1.31, which was not significantly different from the laminar value. The use of a simple flame model and measured turbulent flame speeds indicated that turbulent flashback could involve a smaller effective penetration distance than laminar flashback. Turbulent blow-off velocity was nearly independent of pressure and varied about as the inverse square root of the burner diameter. Of several theoretical treatments, none satisfactorily predicted the observed dependence of blow-off on pressure and burner diameter. The quenching pressure was inversely proportional to burner diameter. The actual pressures were higher than those obtained by other quenching measurements.

Effects of positive flame stretch on the laminar burning velocities of  $O_2/H_2/N_2$  flames at normal temperatures and various pressures and nitrogen dilutions were studied both experimentally and computationally [365]. Measurements and numerical simulations considered freely (outwardly) propagating spherical laminar pre-mixed flames at both stable and unstable preferential diffusion conditions with fuel/equivalence ratios in the range 0.45–4.00, pressures in the range 0.35–4.00 atm, and oxygen concentrations in the non-fuel gas in the range 12.5–21 vol.-%. Measured Markstein numbers were in the range  $-4$  to  $+6$ , implying strong flame/stretch interactions. For air/hydrogen flames, the neutral preferential diffusion condition shifted toward fuel-rich conditions with increasing pressure. Predictions of stretch-corrected laminar burning velocities and Markstein numbers, using typical contemporary chemical reaction mechanisms, were in reasonably good agreement with the measurements.

An apparatus used for the study of expanding spherical flames in  $O_2/H_2$ /inert mixtures was able to extend the initial unburnt sample pressure to 60 atm [366]. Results substantiated previous observations of the propensity of cell formation over the flame surface due to hydrodynamic and diffusive thermal instabilities and provided convincing evidence that wrinkled flames are the preferred mode of propagation in air/hydrogen mixtures at pressures above only a few atmospheres. It was shown that by using helium as the diluent and by reducing the oxygen concentration of the combustible, diffusional thermal instability can be mostly suppressed and the hydrodynamic instability delayed. Stretch-free laminar flame speeds were determined for smooth flames starting at up to 20 atm and were compared with the calculated values, allowing for detailed interpretation of chemistry and transport data. It is remarkable that, as shown in Figure 5 of this paper, the mass burning rate increased with pressure both in the range 1–3 and 10–30 atm, while the fundamental flame speed  $S_u$  increased only in the range 1–3 atm, but decreased at higher pressures of 10–30 atm.

An experimental and numerical study on laminar burning velocities of air/hydrogen flames was performed at low pressures, room temperature and different equivalence ratios [367]. Flames were generated using a small contoured slot-type nozzle burner ( $5 \times 13.8$  mm). Burning velocities were measured using the angle method combined with schlieren photography. Numerical calculations using existing detailed reaction mechanisms and transport properties and an analysis of the intrinsic flame instabilities of hydrogen/air flames at low pressure were performed. Results showed that the behavior of the laminar burning velocity was not regular when the pressure was decreased and that it depended on the equivalence ratio range. The behavior of the laminar burning velocity with decreasing pressure can be reasonably predicted using existing reaction mechanisms; however, changes in the magnitude of the laminar burning velocity were underestimated. It has been found experimentally and confirmed analytically that the intrinsic flame instabilities are reduced when decreasing the pressure to sub-atmospheric conditions.

Laminar flame speeds of air/hydrogen mixtures at sub-atmospheric pressures were measured in a spherical explosion chamber with a volume of 8.2 L and a high-speed camera combined with a schlieren system for flame visualization [368]. Laminar flame velocities were obtained in the range of 4–80% hydrogen in air at initial pressures of 25–1000 mbar. Laminar burning velocity and flame length were correlated with overall reaction order and activation energy.

The validation of available kinetic schemes is of great importance for predicting laminar burning velocities of air/hydrogen flames as a function of pressure and equivalence ratio. Experimental measurements of laminar flame speeds and modeling studies were performed for air/H<sub>2</sub> pre-mixed flames over a wide range of equivalence ratios (0.5–4.0) and pressures (0.2–3 bar) [369, 370]. The wide range in mixture and thermodynamic conditions studied allowed a better understanding of the peculiar behavior of hydrogen flame speeds with pressure. Two detailed chemical kinetic mechanisms for hydrogen combustion were selected. Excellent agreement was observed between calculations and experimental results, confirming the validity of the kinetic schemes selected. The kinetic analyses offered an explanation for the non-monotonic variation of air/hydrogen flame speed with pressure observed in the experiments.

### 3.2.1.3 Burning Velocity of Air/Hydrogen Flames at Elevated Pressures

The laminar burning velocity of pre-mixed air/hydrogen mixtures was measured in a fan-stirred combustion bomb [371]. Unstretched laminar burning velocities and Markstein lengths were obtained at 0.10 MPa for equivalence ratios of 0.4, 0.6, 0.8, and 1.0 using high speed flame imaging. There were difficulties which arose while trying to obtain similar measurements at 0.25 and 0.50 MPa. The turbulent burning velocity was measured at equivalence ratios of 0.4 and 0.8 from explosions carried out at 0.10 MPa with turbulence intensities of 0.8 and 1.6 m/s. Higher turbulent burning velocity ratios were observed for mixtures which yielded lower Markstein lengths in the laminar combustion experiments.

Laminar burning velocities of air/H<sub>2</sub> mixtures have been measured in a spherical explosion bomb with central ignition [372]. Pre-ignition pressures ranged from 0.1 to 1.0 MPa, with equivalence ratios between 0.3 and 1.0. Many of the flames soon became unstable, with an accelerating flame speed, due to thermal diffusive instabilities. This effect increased with increasing pressure. The flame wrinkling arising from the instabilities enhanced the flame speed. A method was described which allowed for measurement of this effect, based on measurements of the flame radii at which the instabilities increased the flame speed. This enabled burning velocities and Markstein numbers to be obtained, devoid of the effects of instabilities. With increasing pressure, the time interval between the end of the ignition spark and the onset of flame instability, the short period during which stable stretched flame propagation occurred, became increasingly short and very high camera speeds were necessary for accurate measurement. Eventually this time interval became so short that first Markstein numbers and then burning velocities could no longer be measured. Such flame instabilities throw into question the utility of for high pressure very unstable flames. The measured values were compared with those predicted by detailed chemical kinetic models of one-dimensional flames.

Modeling of air/hydrogen flames at elevated pressures and temperatures was extended to initial pressures and temperatures up to 8.0 MPa and 950 K, respectively [373]. Laminar burning velocities and Markstein lengths were obtained at the elevated pressures and temperatures. Sensitivity and flame structure analyses showed good agreement between the computed results and experimental data. The study showed that laminar burning velocities were increased with an increase of initial temperature, and they decreased with an increase of initial pressure. With an increase of initial pressure, the onset of cellular instability advanced and the Markstein length was decreased, indicating an increase of flame instability with the increase of initial pressure. Flame instability was insensitive to initial temperature. Laminar burning velocity was dependent on the competition between the main chain branching reactions and the chain termination reaction. The chain branching reactions are the temperature-sensitive reactions, while the termination reaction is a temperature-insensitive reaction. Through the extraction of the overall reaction orders, it was demonstrated that with increasing pressure, the overall reaction orders gave a decreasing trend and then an increasing trend. On the basis of the numerical data, an empirical formula for laminar burning velocity was correlated for the air/hydrogen pre-mixed mixture at elevated pressures and temperatures. The correlated laminar burning velocities were in good agreement with the known experimental results and simulated results with CHEMKIN. The correlation can be used in the calculation of laminar burning velocities at elevated pressures and temperatures.

### 3.2.1.4 Burning Velocity of Air/Hydrogen Flames at Increased Temperatures

The effect of initial temperatures from about 300 to 700 K on the laminar burning velocity of air/hydrogen mixtures was determined from schlieren photographs of open flames [374]. The temperature was raised in two ways: **(1)** by preheating of the hydrogen-air mixtures and **(2)** by simulated adiabatic preburning of part of the hydrogen in air at 300 K so that initial temperatures of 600 and 700 K would be attained for the resulting mixtures of hydrogen, air, water vapor and nitrogen. The following empirical equations for burning velocity  $u$  were determined: For air/hydrogen mixtures, at initial temperatures with preheating to  $T_0$  of 287 to 700 K, with 29.6 vol.-% hydrogen (stoichiometric mixture),

$$u = 0.01011 T_0^{1.721}$$

where  $u$  is the burning velocity in cm/s and  $T_0$  is the pre-ignition temperature, and with 45.0 vol.-% hydrogen (maximum burning velocity mixture),

$$u = 0.09908 T_0^{1.413}$$

The effect of initial unburnt gas temperature on burning velocity of hydrogen flames in air is illustrated in Figure 54. Note that both scales are logarithmic scales which gave a nearly linear relationship with straight lines. This graph is based on data from [375] and [374].

The publications [350, 351] contained a graph showing the burning rate as a function of composition with temperatures as the auxiliary parameter. Those graphs covered a temperature range from 298 to 523 K (25–250 °C). The older publication from [374] covered a wider temperature range from 287 to 700 K and, although it is the older graph, this graph was preferred for illustrating the effect of initial temperature on burning rate in our book. The dependence of burning rates of air/hydrogen flames on initial unburnt gas temperature is illustrated in Figure 55.

The effect of temperature on the adiabatic burning velocities of diluted hydrogen flames has been analyzed using an updated version of the Konnov detailed reaction mechanism for hydrogen [376]. The rationale in selecting the reaction rate constants was provided with emphasis on their unfortunate uncertainties, and the performance of the updated mechanism was compared to a previous version for a wide range of validation cases: **(1)** jet-stirred and flow reactors; **(2)** oxidation, decomposition, and ignition in shock waves; **(3)** ignition in rapid compression machines; **(4)** laminar burning velocities and flame structures. An overall improvement of the mechanism performance was observed, particularly for the shock tube and flow reactor studies. Temperature dependence of the burning velocity,  $S_L$ , is commonly interpreted using the correlation

$$S_L = S_{L0} \left( \frac{T}{T_0} \right)^\alpha.$$

**Figure 54:** Burning velocity of hydrogen in air at elevated temperatures. (Reproduced and modified from [343].)

The updated mechanism was applied to study the behavior of the power exponent  $\alpha$  for  $O_2 + H_2 + N_2$  flames in a wide range of stoichiometry and dilution ratios. The simulations were compared to the available experimental results, either taken from the literature or from the existing burning velocity data. The equivalence ratio and  $N_2$  content in the mixture were found to have significant influence on the temperature power exponent. The dependence of the temperature exponent on the fitting temperature range was observed and discussed. This effect was found to cause significant discrepancies in the burning velocities at high temperatures, if it was based on an empirical correlation.

### 3.2.1.5 Burning Velocity of Air/Hydrogen/Diluent Flames

Measurements of laminar burning velocities of oxygen/hydrogen/inert gas systems have been made using the nozzle burner/schlieren/cone angle method in which un-

**Figure 55:** Temperature effect on burning rate of air/hydrogen flames. (Reproduced and modified from [374].)

burned gas velocity is determined by laser Doppler velocimetry [377]. The nozzle diameters of the burners were 7 or 10 mm. Nitrogen, argon or helium were used as the inert diluent gases. The oxygen mol fraction in oxygen-inert gas mixture,  $X_{OA}$ , was set at 0.209, 0.150, and 0.090. Equivalence ratio,  $\phi$ , was varied between 0.9 and 4.4. The laminar burning velocity of air/hydrogen was obtained in reasonable agreement with previous data. Under conditions of constant  $X_{OA}$  and  $\phi$ , the laminar burning velocity was the highest when helium was used as an inert diluent, followed by argon and nitrogen. The maximum burning velocities under constant  $X_{OA}$  conditions were experienced at  $\phi$  of about 1.8 in all cases of  $X_{OA}$  and inert gases. The variations of the maximum burning velocity with  $X_{OA}$  were essentially linear for every inert gas system.

Laminar flame speeds of  $O_2/H_2/N_2$  mixtures have been determined in the stoichiometric range of ultra-lean to moderately rich, oxygen concentration range of 7.4–30 mol-% of the oxidizer, and pressure range of 0.2–2.25 atm by using a counterflow flame technique [378]. The results were compared with calculated values obtained by using several existing  $O_2/H_2$  kinetic schemes. The results showed that while these kinetic schemes accurately predicted the propagation speeds of high-temperature flames, they substantially underpredicted those of low-temperature flames. While the experimental pressure exponents of the mass burning rates exhib-

ited a minimum point, parabola-like behavior with increasing pressure, indicating the initial, negative influence of the  $\text{H} + \text{O}_2$  termination reaction and the subsequent availability of a positive channel which facilitates radical production, the calculated results failed to predict the increasing trend in the pressure range investigated. It was suggested that existing kinetic schemes may require revision in the intermediate temperature regime strongly influenced by the  $\text{HO}_2^\bullet$  and  $\text{H}_2\text{O}_2$  chemistry.

Laminar adiabatic burning velocities of flames propagating in diluted oxygen/hydrogen/nitrogen mixtures were measured at atmospheric pressure [379]. The oxygen mol fraction in the oxidizer (an oxygen/nitrogen mixture) was varied between 0.07 and 0.1 (7–10 vol.-%) at an equivalence ratio of  $\phi = 1.058$ . Besides the variation in oxygen content, a variation in equivalence ratio from  $\phi = 0.7 - 3.1$  and from  $\phi = 0.7 - 0.95$  was tested at oxygen mol fractions of 0.077 and 0.1077, respectively. The heat flux method was used to determine burning velocities under conditions where the net heat loss of the flat stretchless flame to the burner was zero. A significant difference was noted when comparing the results with experimental data from the literature.

### 3.2.1.6 Effect of Water (Steam) on the Burning Velocity of Air/Hydrogen Flames

One diluent that is always present in air/hydrogen or oxygen/hydrogen flames is water in the form of steam, the combustion product [380]. The effect of water on the burning velocity of air/hydrogen flames was investigated mostly in connection of nuclear reactor meltdown accidents and flammable or explosive hydrogen mixtures accumulating inside the containment shell.

The effect of adding nitrogen, excess hydrogen, and steam on the burning velocity of a pre-mixed stoichiometric air/hydrogen flame at 0.25 atm pressure and an initial gas temperature of 800 °F (720 K) was measured [381]. Whereas addition of nitrogen caused a reduction in burning velocity proportional to the nitrogen added (as expected), the addition of excess hydrogen produced increases in the burning velocity. Water caused only about one-third of the reduction produced by an equivalent volume of nitrogen. On replacing the nitrogen in the air by water vapor on a mol-for-mol basis, the burning velocity increased. (From around 700 cm/s initially) by about  $6 \text{ cm s}^{-1} \text{ mol}^{-1} \text{ mol}^{-1}$  water in the overall mixture.

The burning velocities of air/hydrogen-air and air/hydrogen/steam mixtures as a function of the temperature and composition of the unburned gases were measured by laser Doppler anemometry and schlieren photography using a constant velocity nozzle burner [351]. A two-cyclone in-series particle generator was used to provide a suitable particle seeding rate for the laser Doppler anemometer to measure the flow velocity of the unburnt gas. Burning velocities of air/hydrogen mixtures measured at room temperature agreed well with those reported in the literature. The burning velocity was measured as a function of unburned gas temperature. The addition of steam to an air/hydrogen mixture noticeably decreased the burning velocity. A correlation equation has been derived from the observed burning velocities covering a hydrogen

concentration range of 18–65 vol.-%, a steam concentration range of 0–15 vol.-%, and a temperature range of 296–523 K (23–250 °C).

Laminar burning velocities of lean air/H<sub>2</sub>/steam mixtures near the lower flammability limit were measured by using the pressure-time history of an expanding flame kernel [382]. Although flames in these mixtures are inherently unstable, this difficulty was avoided by using the early pressure rise of the burn. A comparison of results from that method with burning velocities determined from schlieren photographs of the expanding flame kernel gave good agreement. Despite the difficulties, it was believed that the pressure trace method gives results that are useful in modelling nuclear reactor accident scenarios.

The kinetic effects of water vapor addition on the burning rates of H<sub>2</sub> from 1 to 10 atm at flame temperatures between 1600 and 1800 K were measured experimentally and computed numerically [383]. Burning rates were measured using outwardly propagating spherical flames in a nearly constant pressure chamber. Results showed good agreement with other kinetic models for H<sub>2</sub> flames. Both experiments and model simulations showed that water vapor addition caused a monotonic decrease in mass burning rate and the inhibitory effect was more pronounced with pressure. For hydrogen flames, water vapor addition reduced the critical pressure above which a negative pressure dependence of the burning rate was observed. Water vapor addition had the same effect as a pressure increase for H<sub>2</sub> flames, shifting the reaction zone into a narrower window at higher temperatures. For all fuels, water vapor addition increased OH formation via H<sub>2</sub>O + O while reducing the overall active radical pool for hydrogen flames.

Nitrogen dilution and very fine water mist fogs have been suggested as possible methods of mitigating the overpressure rise, should a hydrogen deflagration occur in a vented enclosure in a nuclear power plant. A numerical CFD gas explosion code has been used to simulate the pressure-time curves and the rate of pressure rise generated following the ignition of different oxygen/hydrogen/nitrogen mixtures in a small-scale vented cylindrical explosion rig [384]. The experimental results suggested that total explosion suppression can be achieved.

A mathematical model was fitted and used to estimate the burning velocity of hydrogen diluted with water fog and/or nitrogen. Burning velocities of hydrogen diluted with water fog and/or nitrogen were measured using a cylindrical explosion rig for both unmitigated and mitigated hydrogen-air deflagrations with nitrogen diluted (oxygen depleted) atmospheres and water fog present [385]. The experimental data examined covered both lean and rich hydrogen mixtures and a range of nitrogen dilution levels and water fog densities. The results suggested that a combination of high-density water fog and nitrogen dilution can be extremely effective in reducing the estimated burning velocity especially for hydrogen-rich O<sub>2</sub>/H<sub>2</sub>/N<sub>2</sub> mixtures with equivalence ratios  $\varphi > 1$ , even at relatively modest dilution levels where the oxygen index is reduced to 16%.

It is not possible to safely operate a traditional gas turbine on hydrogen, due to the high risk of flashback. In particular, it is challenging to retrofit conventional gas turbines to enable an efficient and clean usage of hydrogen. In order to use hydrogen as an efficient and clean gas turbine fuel, steam is added at nearly stoichiometric conditions directly into the combustion process, which significantly reduces the flame temperature. The pre-mixed combustion of pure hydrogen diluted with varying amounts of steam for gas turbine applications was modeled using detailed chemical kinetic rate data of the complex oxidation reactions [386]. The effect of steam influenced the third-body reactions with a significant increase of some key radical concentrations. For the assessment of turbulent flames, it was shown that as the heat release spreads, the flame front thickens and the flame extends slightly further downstream with the addition of steam.

The laminar flame speeds of air/hydrogen flames with steam dilution (up to 33 vol.-%  $\text{H}_2\text{O}$ ) were measured over a wide range of equivalence ratios (0.9–3.0) at atmospheric and elevated pressures (up to 5 atm) by an improved Bunsen burner method [387]. Kinetic schemes taken from the open literature were used to calculate the laminar flame speeds and analyze different effects of steam addition. Four mechanisms all underestimated the laminar flame speeds of air/ $\text{H}_2$ / $\text{H}_2\text{O}$  mixtures at medium equivalence ratios while one mechanism provided the best estimates. When the steam concentration was lower than 12 vol.-%, increasing pressure first increased and then decreased the laminar flame speed, the inflection point appeared at 2.5 atm. When the steam concentration was greater than 12 vol.-%, increasing the pressure monotonously decreased the laminar flame speed. The chemical effect was amplified by elevated pressure and it played an important role for the inhibiting effect of the pressure on the laminar flame speed. The fluctuations of the chemical effect at 1 atm were mainly caused by three-body reactions, while the inversion at 5 atm was mainly caused by the direct reaction effect. Elevated pressure and steam addition amplified the influences of uncertainties in the rate constants for elementary reactions, which might be the cause of disagreement between experimental and simulation results.

The combustion properties of hydrogen-based mixtures diluted by nitrogen and steam in spherical expanding flames in a spherical bomb have been studied over a wide range of equivalence ratios, initial temperatures and dilutions at an initial pressure of 100 kPa ( $T_{\text{ini}} = 296363413 \text{ K}$ ;  $\text{N}_2/\text{O}_2$  volume ratio = 3.76, 5.67, 9; vol.-% steam = 0, 20, 30) [388]. From these experiments, the laminar flame speed, the Markstein length  $L'$ , the activation energy  $E_a$  and the Zeldovich number  $\beta$  have been determined. These parameters were also simulated by a computer program in order to verify the validity of the kinetic mechanism. Other parameters such as the laminar flame thickness  $\delta$  and the effective Lewis number  $\text{Le}_{\text{eff}}$  were also simulated. These results will be very useful in the hydrogen combustion hazard assessment for nuclear reactor power plant new designs.

### 3.2.1.7 Burning Velocity of Air/Hydrogen Flames in Zero-*g* or Reduced Gravity

Burning hydrogen or any other combustible in air on the International Space Station or on the Moon or on Mars (remember the Martian making water?) with lack of buoyancy of hot gases would have burning velocities quite different from those on Earth. Experimental observations indicated that regardless of fuel type the gravity effects may be neglected for laminar burning velocities of 20 cm/s and greater.

A combination of microgravity experiments and computational simulations were used to study effects of diluents on the near-limit properties of laminar, pre-mixed air/hydrogen flames under reduced gravity [389]. One of the objectives of this study may have been to identify diluents that are effective as fire suppressants on space stations. The experiments were conducted in a short-drop free-fall laboratory facility that provided at least 450 ms of  $10^{-2}g$  conditions. Outwardly propagating spherical flames were used to measure near-limit laminar burning velocities at various equivalence ratios and pressures with reactants containing varying concentrations of He, Ar, N<sub>2</sub> or CO<sub>2</sub> as fire suppressants. Burning velocities were also computed using a pre-mixed flame code PREMIX with detailed chemical kinetics, transport properties and radiative heat loss based on optically thin flames. Measured and computed results both showed the suppressant effectiveness of diluent gases to increase in the order He < Ar < N<sub>2</sub> < CO<sub>2</sub>. This was attributed to both the increasing specific heats and the decreasing transport rates of the gases. The agreement between measured and computed laminar burning velocities was better than it was near the limit. Sensitivity analyses suggested that inaccuracies in three-body termination rates for

reactions and in mass diffusion coefficients for H<sub>2</sub> diffusion are the most likely explanation for the near-limit differences. Corresponding calculations of laminar burning velocities considered variable transport and thermodynamic properties, a radiation model, and a detailed O<sub>2</sub>/H<sub>2</sub> chemical kinetic mechanism.

## 3.2.2 Burning Velocity of Oxygen/Hydrogen Flames

### 3.2.2.1 Burning Velocity of Oxygen/Hydrogen Flames at Sea-Level Pressure

It is nearly impossible to measure burning velocities of oxygen/hydrogen flames at atmospheric pressure because the flames will transition to a detonation on the first opportunity.

The flame temperature of a stoichiometric flame of oxygen/hydrogen is very hot, which is why this combination of gases is sometimes used in welding torches. However, in rocket engines this combination is always used with a large excess of hydrogen, which suppresses the flame temperature. The burning velocity of oxygen/hydrogen flames goes through a maximum at 25 mol-% O<sub>2</sub>, which is on the fuel-rich side of the stoichiometric composition (33 mol-%).

The maximum burning velocity of ozone/hydrogen flames is about 2.5 times faster than that of oxygen/hydrogen flames.

Small amounts of nitrogen dioxide when added to an oxygen/hydrogen mixture have a marked catalytic effect on both the slow reaction and ignition. Concentrations of the order of 0.05 vol.-%  $\text{NO}_2$  may depress the ignition temperature by several hundred degrees.

### 3.2.2.2 Burning Velocity of Oxygen/Hydrogen Flames at Reduced Pressures

Composition and temperature profiles were measured for lean, near-stoichiometric and rich, low-pressure oxygen/hydrogen flames at 7 and 14 mm Hg [390, 391]. Gas samples were withdrawn from the flame with quartz microprobes having orifice diameters ranging from 50 to 100  $\mu\text{m}$ . Infrared spectroscopic measurements were made searching for  $\text{HO}_2$  and  $\text{H}_2\text{O}_2$  in the wavelength region 1–15  $\mu\text{m}$  on a rectangular  $40 \times 10$  cm burner.  $\text{HO}_2$  concentration was below the detection limit of 0.01 mol-% but  $\text{H}_2\text{O}_2$  was found at 0.02 mol-%. A kinetic mechanism was proposed consisting of 6 bimolecular and 4 trimolecular reactions for which rate constants and activation energies were known.

### 3.2.2.3 Burning Velocity of Oxygen/Hydrogen Flames at Increased Pressures

A mechanism consisting of 18 elementary chemical reactions was demonstrated to give a complete quantitative description of the concentration, temperature, and pressure dependence of the flame velocity in  $\text{O}_2/\text{H}_2/\text{N}_2$  mixtures [392]. Whereas concentration and temperature dependence showed the expected behavior, the pressure dependence was determined by two different chain reaction mechanisms occurring simultaneously. At low and at high pressures the pressure exponent of the flame velocity was positive in agreement with simple flame theory. In between there was a transition region with negative pressure exponents due to the change of the chain reaction mechanism, which does not contradict simple flame theory as sometimes asserted in the literature. The partial equilibrium assumption was shown to be valid only at temperatures  $T > 1700$  K, whereas at lower temperatures this hypothesis failed by orders of magnitude.

A study of a similar reaction mechanism consisting of 25 elementary reactions included a sensitivity analysis of the influence of individual elementary reactions involved in the mechanism [393].

## 3.2.3 Effect of Diluents on the Burning Velocity of Oxygen/Hydrogen Flames

Laminar flashback was studied for hydrogen-argon-“air” and hydrogen-helium-“air” systems over a range of pressures [364]. These data contributed toward a general consideration of the pressure dependence of flashback for several fuel-oxidant systems. No relation was found between the critical boundary velocity gradient at 1 atm and its pressure exponent. However, the critical flashback gradient at a pressure of 1 atm and

an equivalence ratio of 1 decreased exponentially with the reciprocal of the adiabatic flame temperature in the manner of a chemical reaction rate.

### 3.2.3.1 Effect of Water (Steam) on the Burning Velocity of Oxygen/Hydrogen Flames

One diluent that is always present in air/hydrogen or oxygen/hydrogen flames is water in the form of steam, the combustion product [380]. The effect of water on the burning velocity of oxygen/hydrogen and air/hydrogen flames was investigated.

Radiolysis of water in the cooling loop of nuclear power reactors during normal operation of the reactor forms a mixture of oxygen, hydrogen, and steam. The radiolysis gas consisting of a stoichiometric hydrogen-oxygen mixture diluted with steam at different temperatures and pressures is a typical gas composition for the closed loop system of Boiling Water Reactors (BWR). There are occasional radiolysis gas explosions relevant to BWR operating conditions: initial pressures up to 70 bar and temperatures up to 570 K [394]. The gas has to be vented periodically on the low-pressure side of the turbine after the effluent has passed the cooling tower.

In the case of accidental meltdown of nuclear reactors, the hydrogen is formed by reaction of hot steam with the zirconium cladding of the fuel rods, and the containment vessel may be filled with a mixture of air, hydrogen, and steam. In certain postulated loss of coolant nuclear reactor accidents, hydrogen gas from zirconium-steam reactions in the reactor core can leak into the containment building to form a combustible mixture. If the hydrogen mixes with air and is ignited, the resulting explosion pressure could pose a threat to the integrity of containment structures and other essential equipment. The overpressure developed in such accident scenarios depends on the burning rate of the combustible mixture and the presence or absence of steam, usually expressed in terms of its laminar burning velocity.

The exhaust of gas generators in closed cycle LOX/LH2 engines consists of steam and unburnt hydrogen that is then fed into the main engine. The burning velocities of  $O_2/H_2/H_2O$  steam mixtures were measured repeatedly under a wide range of conditions.

A comparative study of the effects of diluents on the burning velocity of  $O_2/H_2$  mixtures has been carried out, focusing on the effect of steam on burning velocity and flame structure [395]. Burning velocities were measured by the nozzle burner, cone angle method with particle tracking by laser doppler anemometry for a range of stoichiometries and diluent fractions (He, Ar,  $N_2$ , steam) for air/ $H_2$  mixtures containing up to 50% steam. An empirical correlation was obtained which accurately predicted the physical effects of diluents (flame cooling and heat transport) on burning velocity:

$$S_u \left( \frac{\alpha_0}{\alpha} \right)^{\frac{1}{2}} = S_{u0} \left( 1 - \frac{X}{X_L} \right)$$

where  $S_u$  is the laminar burning velocity,  $\alpha$  is the thermal diffusivity,  $X$  is the mol fraction of diluent,  $X_L$  is the diluent fraction sufficient to inert the mixture and suffix 0 denotes the undiluted mixture. This correlation underestimated the burning velocity for

steam diluent by 20%, indicating that steam influences the burning velocity by mechanisms other than flame cooling and heat transport. Using a one-dimensional flame model, the changes to the flame structure caused by the addition of steam were calculated and indicated that steam effects a redistribution of heat release in the flame. This is caused by the high third-body efficiency of steam in the exothermic reaction

Steam increases the rate of this reaction and, subsequently, the rates of a cycle of exothermic reactions involving  $\text{HO}_2$  in the preheat region of the flame. The result is a steeper temperature profile (i.e., a thinner flame) and an increased burning velocity. Sensitivity analysis indicated this mechanism produces the same effect on burning velocity as is observed experimentally upon adding steam.

The burning velocities of stoichiometric  $\text{O}_2/\text{H}_2$ /steam mixtures with steam concentrations up to 70 vol.-% at elevated pressures and temperatures have been measured and the results compared with numerical calculations [396]. The influence of thermal radiation and kinetic mechanisms on the burning velocity and the detonability of such mixtures at high initial pressure and temperature was evaluated.

The radiolysis gas consisting of a stoichiometric oxygen/hydrogen mixture diluted with steam at different temperatures and pressures is a typical gas composition and a potential hazard for the closed loop system of BWR. There are significant gaps in the experimental data on radiolysis gas explosions relevant to BWR operating conditions. Critical conditions for the flame acceleration and detonation onset of stoichiometric hydrogen-oxygen-steam mixtures at pressures up to 70 bar and temperatures up to 573 K have been calculated. A problem was that critical conditions for the flame acceleration and deflagration to detonation transition (DDT) were only based on experimental data obtained at initial pressures up to 3 bar. Flammability limits, flame acceleration limits and DDT limits at the characteristic scale  $L = 100$  mm were calculated for hydrogen-oxygen mixtures at the initial temperature of 573 K (300 °C) and for two different initial pressures with and without addition of steam [397]. The experiments have been performed with hydrogen-oxygen mixtures at pressures up to 72 bar and temperatures of 383, 423, 473, and 573 K (110, 150, 200, and 300 °C) in a 121-mm I.D., 8-m long tube, and also in a 24-mm I.D., 4-m long tube.

Stoichiometric oxygen/hydrogen mixtures diluted with steam up to 85 mol-% have been tested in a spherical explosion chamber with an inner diameter of 25 cm using the pressure method and high-speed shadow cinematography [398]. The experimental data on the laminar burning velocity were compared with numerical calculations that used different H/O reaction mechanisms based on the Lutz, GRI-Mech 3.0, Li and Warnatz kinetic schemes. Non-monotonic pressure dependence and strong suppressing effect of steam dilution on laminar flame velocity was found both experimentally and numerically. The best consistency with the experimental measurements of the laminar flame velocity at elevated pressures and temperatures in the presence of high steam concentrations was found for the Lutz H/O mechanism.

### 3.2.3.2 Flame Speed of Oxygen/Hydrogen/Diluent Flames

One ternary oxygen/hydrogen/inert gas diluent mixture of particular interest as a rocket propellant is the  $O_2/H_2/He$  mixture also known as Tridyne (see *Encyclopedia of Monopropellants*, chapter “Other Monopropellants”).

This mixture is formulated to avoid the flammable range. In order to safely formulate Tridyne-like gas mixtures, the flammable range and the flame speed of  $O_2/H_2/He$  mixtures have to be known.

Experimental and calculated laminar burning velocities of  $O_2/H_2/He$  mixtures with equivalence ratios of 0.6–4.0, initial pressures of 0.1–0.5 MPa, initial temperature of 373 K, and dilution ratio of 7.0 were compared [399]. Laminar burning velocities changed non-monotonically with the increasing initial pressures at equivalence ratios of 1.0–3.0. The decrease of overall reaction orders can explain the non-monotonic relationship between the laminar burning velocities and initial pressures. Consumption and production rates of both  $H^\bullet$  and  $HO_2^\bullet$  radicals were obtained to explain the decrease of overall reaction order. The three-body reaction

gained more  $H^\bullet$  radicals in competition with

producing more  $HO_2^\bullet$  radicals. Through the reaction pathway analysis, the restraint in production of both OH and H lead to a reduced radical pool. The lower reaction pool would restrain the overall reaction and lead to the reduction of overall reaction order and the non-monotonic behavior of the laminar burning velocity.

### 3.2.4 Radiation Emission Spectra of Oxygen/Hydrogen Flames

Hot flames of oxygen/hydrogen combustion emit a wide range of radiation, although not as luminescent in the visible range as oxygen/hydrocarbon flames. Radiation emissions from oxygen/hydrogen flames have been studied as a diagnostic tool, to identify reactive species in the combustion reaction, to develop fire sensing apparatus and to protect fire-fighting crews from unseen hazards.

Experiments were conducted to study the establishment of equilibrium in  $O_2/H_2$  detonations, especially with respect to the rotational and vibrational degrees of freedom [400]. For this purpose, the emission spectra of different detonations were recorded both photographically and electronically with a photomultiplier tube and a moving slit. Temperatures of rotation and vibration were calculated where possible. In all these experiments, the initial gas mixtures were at room temperature and atmospheric pressure. The spectra were studied in three different spectrographs. A comparison of the spectra of burner with spectra of detonations showed that detonation spectra were less resolved than the burner flame spectra. Transitions with higher quantum numbers were stronger in detonations than in flames.

The emission spectra of oxygen/hydrogen and air/hydrogen flames at 0.1–1 atm exhibit a system of bands between 852 and 880 nm, which were assigned to the  $\text{H}_2\text{O}_2$  molecule vibrationally excited into the overtone region [401]. This molecule results from the reaction

The overtone region also contains bands at 670 and 846 nm, which were assigned to the vibrationally excited  $\text{HO}_2^\bullet$  radical. This radical results from the reaction between  $\text{H}^\bullet$  and  $\text{O}_2$ . The  $\text{HO}_2^\bullet$  radicals resulting from  $\text{H}_2$  combustion inhibited by small amounts of propylene as a free radical scavenger were initially in vibrationally excited states.

There are two dominant types of radiation from hydrogen flames under rocket engine combustion conditions: ultraviolet and blue radiation [402]. The intensity of the spectral lines is pressure dependent [403]. The hyperfine structure of the OH emission lines is useful for combustion and plume diagnostics [404].

### 3.3 Analysis of Hydrogen

The preferred method for the analysis of contaminants in hydrogen gas is by gas chromatography, in particular with flame ionization detectors for organic contaminants (methane, oil).

The other analytical task is the determination of the orthohydrogen: parahydrogen ratio which changes with the conditions during liquefaction and changes with storage time if the mixture has not achieved equilibrium at the normal boiling point of hydrogen. One must know the orthohydrogen: parahydrogen ratio for predicting evaporation losses from large hydrogen tanks. The thermal conductivity of orthohydrogen and parahydrogen gas is quite different, so that this property can be used for determining the orthohydrogen: parahydrogen ratio. The difference in thermal conductivity is most pronounced at 150 K. The method uses a thermal conductivity bridge detector similar to the katharometers used in the first generation of gas chromatographs [405–407].

Parahydrogen content in  $\text{GH}_2$  can be determined by thermal conductivity type in-stream analyzers typically already installed in the manufacturer's liquefaction plant system. Analyzers must be calibrated integrally by the appropriate use of temperature-controlled catalyst beds.

The output of a thermal conductivity cell to measure the parahydrogen concentration in a mixture of para and orthohydrogen gas had been previously assumed to be linear, but this assumption can lead to systematic errors of up to 5.6% in the determination of the parahydrogen concentration. This requires separate calibration procedures [408, 409].

Raman spectroscopic measurement of the ratio of the first two rotational bands of hydrogen at 355 and 586 cm<sup>-1</sup> corresponding to parahydrogen and orthohydrogen, respectively, has been used to determine the parahydrogen content during a production process and a reaction [317]. The results obtained using Raman spectroscopy were compared to those obtained by low-field nuclear magnetic resonance (NMR) spectroscopy. While the results were in good agreement, Raman analysis had several advantages over NMR for this application. The Raman method does not require a reference sample, as both spin isomers (ortho and para) of hydrogen can be directly detected, which simplifies the procedure and eliminates some sources of error. This offers the potential of an industrially compatible method for determining parahydrogen content in applications that require the storage and usage of hydrogen.

### 3.3.1 Specification Requirements for Hydrogen

Military Specification MIL-PRF-27201D covers both gaseous (type I) and liquid (type II) hydrogen [410]. The purity requirements for hydrogen are listed in Table 39.

**Table 39:** Purity requirements for hydrogen per MIL-PRF-27201D

| Constituent                             | Composition                      | Analytical method           |
|-----------------------------------------|----------------------------------|-----------------------------|
| Hydrogen assay                          | 99.995% by volume, min.          | As recommended by CGA G-5.3 |
| Parahydrogen                            | 95% by volume, min. <sup>a</sup> | Thermoconductivity detector |
| Impurities                              | 50 ppm by volume, max.           | As recommended by CGA G-5.3 |
| Nitrogen, water, and total hydrocarbons | 9 ppm by volume, max.            | As recommended by CGA G-5.3 |
| Oxygen and argon                        | 1 ppm by volume, max.            | As recommended by CGA G-5.3 |
| Helium                                  | 39 ppm by volume, max.           | As recommended by CGA G-5.3 |
| Carbon monoxide and carbon dioxide      | 1 ppm by volume, max.            | As recommended by CGA G-5.3 |

<sup>a</sup> Applies to liquid hydrogen only

CGA = Compressed Gas Association

### 3.3.2 Gas Chromatographic Analysis of Hydrogen

Gas chromatographic analysis of hydrogen in gas mixtures using helium as the carrier gas will give erroneous results because the thermal conductivity of the two gases is so similar. More accurate results can be obtained by using argon as the carrier gas, but sensitivity for all other gases is then reduced and the katharometer can only be operated at a lower current.

Catalytic conversion of parahydrogen to normal hydrogen is essential to improve the accuracy of gas chromatographic determination of impurities in LH2 [411]. Fe<sub>2</sub>O<sub>3</sub> or Ni catalysts were used for the conversion.

### 3.3.3 Hydrogen Gas Detectors

Hydrogen from undetected leaks has a tendency to collect under roofs where there may be ignition sources leading to a fire or an explosion. Hydrogen gas detectors would typically be mounted under the ceilings of buildings where hydrogen is handled.

There are hydrogen gas detectors that can trigger an alarm to detect hydrogen leakage or spillage near storage areas. Two hydrogen gas detectors were evaluated in experiments simulating likely operating conditions [412]. Both units were console types sampling by diffusion and convection. When exposing the instrument to increasing concentrations from 4 to 100% hydrogen in air, followed by exposure to decreasing concentration, the calibration had shifted by a substantial amount.

One type of flammable vapor in an air detector uses catalyst coated beads. In the presence of flammable vapors even below their lower flammable limit, the warming of the catalyst bead is sensed by a series of thermistors and triggers an alarm [413, 414]. These sensors work for hydrogen or hydrocarbon vapors. In a catalytic sensor, a palladium and/or platinum catalyst is used to facilitate the combustion of hydrogen with oxygen. A sensing element detects the heat of combustion.

In electrochemical sensors, liquid or solid electrolytes are surrounding a sensing electrode and a counter electrode and in contact with the air to be monitored. Reaction with hydrogen produces an electric current. The air containing the hydrogen gas must flow through a gas permeable membrane to reach the electrolyte. In semiconducting hydrogen gas sensors the gas reacts with chemisorbed oxygen in an oxide semiconductor material, such as tin oxide, and changes the resistance of the material.

In thermal conductivity sensors similar to those used in gas chromatography detectors, the rate of heat conduction from a heat source into the surrounding environment is dependent on the thermal conductivity of that gas environment. Hydrogen has a much higher thermal conductivity than air.

In mass spectrometer monitors, the gas is ionized and then accelerated through an electric field along a curved path. The amount of curvature induced by the electric field is dependent on the mass of the particle and is used to separate the particles by mass. A detector is placed in the path of the desired gas to be measured. Various other sensor techniques for hydrogen leakage and fire detection are available [415, 416]; Table 40.

A solid-state potentiometric hydrogen gas sensor based on hydronium Nasicon, a hydrogen ion conducting solid electrolyte, incorporated a silver-based reference electrode and a palladium working electrode [417]. The sensor was robust, simple, fast, and capable of detecting hydrogen concentrations from at least 0.01 to 100%, a range of four orders of magnitude, in oxidizing and non-oxidizing atmospheres.

A review of electrochemical hydrogen sensors included amperometric, potentiometric, and conductometric sensors [418]. There are sensors with liquid electrolytes and sensors with polymer electrolytes. There are solid-state sensors for hydrogen, but some of those need to be heated all the time.

**Table 40:** Sensitivity limits of hydrogen detectors.

| Minimum detection limits, average values |                    |                    |       |                    |                    |                   |
|------------------------------------------|--------------------|--------------------|-------|--------------------|--------------------|-------------------|
| Principle                                | In air             |                    |       | In nitrogen        |                    |                   |

Data source: [415].

There are numerous sensors reported in the literature for hydrogen detection. In one review, these sensors were classified into eight different operating principles [419]. Characteristic performance parameters of these sensor types, such as measuring range, sensitivity, selectivity, and response time were reviewed and the latest state of technology was reported. Testing and validation of sensor performance were described in relation to standardization and use in potentially explosive atmospheres specifying the requirements on hydrogen sensors for practical applications.

## 4 Materials of Construction for Hydrogen

This chapter summarized the choice of materials of construction for handling of liquid and gaseous hydrogen, both structural materials and insulating materials to keep the cold in and to keep the heat out. The main problem in the selection of materials of construction for cryogenic hydrogen systems is the embrittlement of materials that can lead to fractures under moderate loads and vibrations. The same problems could be encountered with other cryogenic liquids.

There are many sources of information on the selection of materials (metallic and non-metallic materials) for operation at cryogenic temperatures, foremost of all the Cryogenic Material Properties Database [420]. This database is a critical evaluation

of existing experimental measurements on the properties of engineering materials at cryogenic temperatures. Equations are given for the recommended property value as a function of temperature. There were many sources of information on materials of construction for liquid hydrogen, most of those from the Cryogenics Laboratory in Boulder, CO, USA operated by the National Bureau of Standards. During the period 1998–1999, the Chemical Propulsion Information Agency (CPIA) released four versions of the Cryogenics Information Retrieval System in CD form, including the NBS Cryogenics Database and a wide range of other literature sources, eventually containing 133000 citations [421].

Since the book at hand is mostly a chemistry book and not a materials science book, these sources are offered just as references recommended for further study, but the technical details cannot be provided in this book. Those mechanical considerations in the selection of cryo-capable materials are essentially the same for LH<sub>2</sub> or LOX, LN<sub>2</sub>, and LNG.

## 4.1 Metals for Hydrogen Service

Compared to natural gas transmission lines and storage tanks, composition, heat treatment, and weldability requirements are more severe for materials for hydrogen transport [422, 423]. Some pressure vessel steels are susceptible to hydrogen embrittlement and thus seamless vessels and/or protective liners are required. High-strength resistant steels must be developed for compressors, valves, and related equipment.

The embrittlement of metals exposed to hydrogen is not only due to the low temperature (all materials become brittle at low temperatures) but also due to hydrogen embrittlement where hydrogen diffuses into the metal and forms interstitial hydrides. The formation of interstitial hydrides causes some metals to swell and fall to powder once they are exposed to hydrogen. This is very catastrophic for structural materials but has been used with advantage for storage of compressed hydrogen in iron/titanium alloys.

### 4.1.1 Metals Acceptable for Hydrogen Service

Hydrogen is not corrosive and does not have special requirements in the selection of materials; however, hydrogen embrittlement of materials and loss of elasticity at the very low temperatures will present unique problems that are not usually observed with other rocket propellants.

One will look for metals which retain some elasticity even at the very low temperatures of boiling liquid hydrogen at 20 K. Metals accepted for tanks and components for liquid hydrogen service include stainless steel CRES-321, CRES-347, and CRES-304, in addition to Inconel, monel, nickel, and aluminum. Carbon steels become very brittle

at low temperatures. Aluminum/magnesium alloys Al-5052, Al-5083, Al-5086, Al-5164, and Al-5456 have been used for liquid hydrogen tanks.

Titanium alloys combine good strength with light weight [424]. A large 26000-L (7100 gallon) tank was made from titanium [425–427]. The oxygen, carbon, nitrogen, and iron content of titanium alloys for cryogenic hydrogen service must be very low. Best results were obtained with a Ti-5Al-2.5Sn alloy, which allows a weight saving of 30–35% compared to aluminum or steel vessels [428]. Tantalum and columbium alloys have been evaluated for liquid hydrogen service [429]. Various coatings were tested as hydrogen barriers. It is desirable that materials for construction of hydrogen facilities (tanks, lines, valves) should have a low heat capacity such that the component can cool down quickly and not so much liquid hydrogen is lost by evaporation during cooldown.

The evaporation losses during storage are reduced mostly by surrounding a tank with an insulating material with very low thermal conductivity (see section “Insulating Materials for Liquid Hydrogen Service”). In addition to using a thermal insulation with low thermal conductivity, it helps to select materials with low thermal conductivity for the design of the tanks and lines. In particular, support structures (struts, brackets) which carry the load through the thermal insulation (which is usually not load-carrying) should be made of materials with low thermal conductivity so they do not act as a bridge for heat flow.

The coefficient of thermal expansion should be low to prevent excessive stretching and shrinking during thermal cycles, causing microscopic thermal internal stress and macroscopic local stress concentrations in structures and container walls. The temperature fluctuations and material strains during filling and emptying of LH<sub>2</sub> tanks are more severe than with any other cryogenic rocket propellant [430, 431].

#### **4.1.2 Low Temperature Phase Changes**

Some metals undergo phase changes at low temperatures and changes of the crystal lattice structure with subsequent loss of mechanical strength. This is just a temperature problem and would occur with any cold fluid, not just with liquid hydrogen. Such phase changes take place very slowly and are often noticeable only after repeated temperature cycling. A martensitic transformation occurs in austenitic stainless steels when they are strained and the amount of the ferromagnetic phase appearing is particularly important when the deformation is produced at low temperatures [432]. The phase change from a gamma to an alpha phase is quite distinctly observable with a steel of the 18-10 type [433].

#### **4.1.3 Tensile Strength of Metals at Low Temperatures**

Tensile tests of 20 different metal coupons at room temperature, 200, 77, and 20 K (–100, –320, and –423 °F) temperature were conducted on a 60000-lb<sub>f</sub>-capacity Baldwin-type hydraulic-operated tensile machine in accordance with Method 211.1

of Federal Test Method Standard No. 151A, which is essentially identical with ASTM Specification E8-61T [434].

#### 4.1.4 Shear Strength of Metals at Low Temperatures

The following references give additional information on materials of construction for liquid hydrogen installations and flight vehicles: [435, 436].

#### 4.1.5 Hypervelocity Projectile Impact on Cryogenic Tank Walls

Orbital debris and micrometeorites constitute an omnipresent hazard for anything that moves in orbits in space. An experimental and analytical investigation was conducted to determine the structural behavior of cryogenic tank wall materials under simulated meteoroid environments and to develop engineering methods defining tank working stresses under the impact of hypervelocity projectiles [437]. The boundary limits between safe fracture and catastrophic fracture were established for 2219-T87 aluminum and Ti-5Al-2.5Sn (ELI) titanium alloy used in cryogenic propellant tanks. Safe fracture boundary limits were established for a wide range of meteoroid masses and velocities. Hypervelocity projectiles of known mass were launched by a light-gas gun to simulate meteoroid impacts. Impact tests were conducted with the tank walls at 77 K (−320 °F) and numerous tests were conducted at 20 K (−423 °F).

### 4.2 Metals Not Acceptable for Hydrogen Service

#### 4.2.1 Hydrogen Embrittlement of Metals

Hydrogen embrittlement causes a decrease in the fracture toughness or ductility in certain metallic materials due to the mobility of atomic hydrogen. Hydrogen must first permeate within a metal for hydrogen embrittlement to occur. Permeation of hydrogen gas in metals begins with the absorption of a hydrogen molecule upon the metal surface and dissociation into atomic hydrogen. Once hydrogen ions (H<sup>+</sup>) form, they readily diffuse through interstitial spaces in the metal crystal lattice. The interaction between hydrogen and metals can result in the formation of solid solutions of hydrogen in metals, solid compounds as hydrides, reforming into molecular hydrogen, or gaseous compounds with other elements in the metal. Some metals undergo noticeable swelling at this point. There are several types of hydrogen embrittlement: **(1)** hydrogen environmental embrittlement, **(2)** hydrogen internal embrittlement, and **(3)** hydrogen reaction embrittlement. Hydrogen embrittlement of metals may be the result of one or a combination of these three processes.

Sensitivity to hydrogen embrittlement is influenced by numerous parameters, including plastic deformation, cyclic loading, hydrogen purity, temperature, and pressure. Hydrogen embrittlement is a major concern for ferritic steels and occurs at ambient temperatures and elevated pressures. The problem is exacerbated when

the steel is subjected to mechanical stresses. The embrittlement processes take place more quickly on freshly generated metallic surfaces that are likely to form at surface defects or other stress raisers as a result of stress-induced local plastic deformation processes.

#### **4.2.2 Hydrogen Permeation of Metals**

Iron-titanium alloys are known to absorb hydrogen as intermetallic hydrides and are used as hydrogen storage media. In view of this property, it should not be surprising that hydrogen can permeate titanium metal. While titanium has proved to be a good material for containers for liquid hydrogen, calculations of the rates of permeation of gaseous hydrogen through titanium indicate that there may be practical limits of temperature, pressure, and time that must be recognized in designing pressure containers for hydrogen. On the basis of reported data, titanium and its alloys cannot be recommended as container materials for hydrogen for long-term service much above 366 K (200 °F) [438, 439]. For short-term service, the permeation to hydrogen may be low up to temperatures near 533 K (500 °F) and at low pressures.

#### **4.2.3 Metals Fatigue at Cryogenic Temperatures**

Metals need to maintain a certain flexibility to yield to stresses and deformations resulting from uneven thermal expansions and shrinking during their service life in a liquid hydrogen system. Many metals suffer fatigue during repeated flexing [440, 441]. This problem is not unique for metals at liquid hydrogen temperatures but affects all metals in all cryogenic environments. Strain-cycling fatigue behavior of 10 different structural alloys and metals was investigated in liquid helium (4 K), in liquid nitrogen (78 K), and in ambient air (300 K) [442]. At high cyclic lives, fatigue resistance increased with decreasing temperature for all the materials investigated. At low cyclic lives, fatigue resistance generally decreased with decreasing temperature for the materials investigated. Only for Inconel 718 did fatigue resistance increase with decreasing temperature over the entire life range investigated.

### **4.3 Composite Materials for Liquid Hydrogen Tanks**

Hydrogen tanks made of polymer-matrix composite material have been advertised as an enabling technology for reducing the dry weight of launch vehicles. For many decades it has been attempted to replace metal in cryogenic tanks by lightweight organic polymers, usually reinforced with inorganic fibers (glass or carbon fiber reinforced composites). The advantage of plastics over metal would be not only lighter weight but also reduced thermal conductivity [443]; however, most plastics become very brittle at the low temperatures and are susceptible to cracking. Remember the

science fair trick where a tennis ball soaked in liquid nitrogen and dropped on the floor shatters in many pieces like glass!

First evaluation of composite materials for liquid hydrogen tanks started in the 1960s, measuring thermal expansion [444], tensile strength at temperatures down to 20 K [445] and hydrogen gas permeability and vapor barrier materials [446]. Development has started on composite-overwrapped pressure vessels for cryogenic service [447, 448], but in the half century that has passed since it has unfortunately not yet progressed to a flight-ready design.

One difficulty with the use of composites is the gas permeability. Hydrogen diffuses readily through organic polymers. Organic polymers have to be laminated with metal foil as diffusion barriers [446, 449].

Composite liquid hydrogen flight tank development had been underway for several years. It began with the National Aerospace Plane (NASP) program, continued several years with work for Single-Stage-to-Orbit (SSTO) Reusable Launch Vehicle (RLV) studies and technology development, including the production of a complex, multi-lobed composite tank for the X-33 program, and continuing for 2<sup>nd</sup> Gen RLV applications under NASA's Space Launch Initiative (SLI).

#### 4.3.1 Hydrogen Permeability of Composite Tank Wall Materials

A fundamental issue for composite liquid hydrogen tanks is the hydrogen permeability of the composite material. Hydrogen permeability was studied in the early days of NASP and results were encouraging enough to proceed with unlined tank development. Then permeability work was relatively dormant for several years under the erroneous assumption that the unlined composite materials were sufficiently impermeable. The high-profile ground test failure of the X-33 hydrogen tank, however, is believed to be a direct result of excessive hydrogen permeation into the honeycomb cells of the sandwich tank wall. As the tank warmed after it was drained, the hydrogen that had permeated into the sandwich from the inside of the tank plus, perhaps, some air that had been cryopumped in from the outside, expanded, and the pressure inside the cells increased, eventually causing a debonding of the core and inner composite face sheet. The failure and subsequent investigation then brought the permeability issue back to center stage [450]. Some of the cryogenic permeability studies referenced here may apply to other cryogenic propellants in addition to liquid hydrogen.

A key development task for composite propellant tanks is to prevent the leakage of hydrogen through the composite material, which is a function of the tank manufacturing method, mechanical load, internal damage in the material due to thermal stresses (microcracks), and the temperature at which the tank must operate. A method was developed for measuring leakage through a geometrically complex shape at cryogenic temperatures and under mechanical load and used to measure helium and hydrogen leakage through the X-33 liquid hydrogen tank wall [451]. Both hydrogen and helium leak tests that were performed on two specimens taken from a discarded segment of

the X-33 tank structure and results showed that the leak rate varied with the applied mechanical load. The level of hydrogen leakage was shown to be significantly higher than the helium leakage and to exceed the acceptable leak rate for a vehicle like the X-33 liquid hydrogen tank by an order of magnitude. After the expensive lesson of the X-33 tank failure, studies of composite liquid hydrogen tanks ("cryotanks") resumed for a second-generation RLV [452].

Leak characteristics of carbon fiber reinforced plastic (CFRP) cross-ply laminates were experimentally investigated under biaxial loadings using an in-plane biaxial testing system [453]. Permeability through the damaged laminate under biaxial stresses was measured with a leak detection system and ultrasonic C-scan was used to inspect the matrix cracking in the specimens. Experimental results revealed that leakage through the damaged laminate is in correlation with the amount of damage and depended not only on load levels but also on biaxial load ratios.

Helium permeability in CFRP cross-ply laminates was measured in relation to crack density and applied biaxial loads [454]. The results of the experiments indicated that stacking sequences of CFRP laminate influenced not only matrix crack development but also leakage prevention. Permeability through the damaged laminates increased in accordance with damage development and increasing rate of permeability in connection with the strains was dominated by the external biaxial loads.

A computational fluid dynamics (CFD) model was developed to predict leakage through a damaged laminate [455]. Leakage under combined thermal and biaxial mechanical loadings was predicted with the estimated delamination length.

Thermal residual stresses, internal pressure stresses and acceleration stresses during launch were evaluated and quantified for cryogenic composite fuel tank designs [456]. Both failure initiation and progression of a graphite/epoxy laminate system and a graphite/BMI laminate system were investigated using the non-isothermal classical laminate and plate theory and the maximum stress failure criterion. The thermal residual stresses in the transverse direction are the dominant stresses on each ply in the launch stage. After initial ply cracking, through-the-thickness temperature change of a laminate related to fuel leakage as well as a laminate stiffness matrix change was applied to the progressive failure analysis. The fuel leakage-based progressive failure analysis showed a higher number of initial ply cracking does not necessarily mean a higher chance of matrix cracking in all plies at an initial exposure to 20 K (−253 °C) and 1500 kPa. In terms of complete laminate matrix cracking, however, the graphite/epoxy laminate was more resistant to transferring stresses to other plies than the graphite/BMI laminate.

A test system has been assembled to accurately measure the hydrogen permeability of laminates with microcracks and to establish a correlation between damage state and hydrogen gas permeability [457]. The test environment used to induce the microcrack damage consisted of mechanical cycles at both room temperature and at cryo-

genic temperature. Permeability was found to be clearly dependent on both applied mechanical loads and test temperature with the highest leak rate occurring at the cryogenic temperature condition.

Another experimental study of the correlation between damage state and hydrogen gas permeability of laminated composite materials under mechanical strains and thermal loads examined a composite material specimen that had been mechanically cycled at room temperature to induce microcrack damage [458]. Crack density and tensile modulus were observed as functions of number of cycles. Damage development was found to occur most quickly in the off-axis plies near the outside of the laminate. Permeability measurements were made after 170000 and 430000 cycles. Leak rate was found to depend on applied mechanical strain, crack density and test temperature [459].

In order to develop a correlation between thermal fatigue-generated networks of transverse microcracks and the permeability of carbon fiber, polymer matrix composites with epoxy and bismaleimide polymer matrices were cycled between liquid nitrogen temperature (77 K = -196 °C) and elevated temperature [460]. The samples were then optically examined for microcracks and evaluated for their tendency for low-pressure helium gas leakage in a fluid containment application.

A new composite concept that can be used to create CFRPs with high hydrogen gas barrier performance for applications in the cryogenic tanks of fully reusable space transportation systems consists of a non-metallic crystal layer, which is actually a dense and highly oriented clay crystal laminate [461]. Preliminary test results showed that the hydrogen gas barrier characteristics of this material after cryogenic temperature shocks and cyclic loads were still better than those of other polymer materials by approximately two orders of magnitude.

Hybrid fiber composites with carbon and Kevlar<sup>®</sup> fabric were explored as means to reduce the influence of thermal gradients and in order to enhance the material performance when cryogenic propellant fuels are stored in space launch vehicle applications [462]. Preliminary studies of tensile and flexural strength had indicated that carbon and Kevlar<sup>®</sup> woven fiber composites are suitable materials for cryogenic temperatures. The pristine mechanical properties of carbon composites changed within a maximum of 3–4% after initial cryogenic exposure during the fueling stage, while Kevlar<sup>®</sup> composites changed 17%.

#### 4.3.2 Insulation of Composite Propellant Tanks

Insulation can be applied either internally or (more commonly) externally. If the insulation is internal to the tanks, the outside load-bearing shell remains at higher temperatures and remains more flexible and hopefully will not embrittle due to the cold.

The use of fiber-glass-reinforced plastics as a structural material surrounding internally located foam insulation for liquid hydrogen propellant tanks was investigated

and experimentally evaluated in a sub-scale cryogenic tank [463]. The tank consisted of three main components: a structural shell of filament-wound fiber glass, an internal insulation system of polyurethane foam encapsulated in a vacuum-tight jacket of aluminum-Mylar-aluminum foil laminate, and an impermeable liner of the same laminate. Liquid-hydrogen boil-off tests were used to determine the thermal performance and pressure-cycling tests were used to evaluate structural performance. Hydrogen gas should not be allowed to diffuse into pores in internal insulation. Hydrogen gas has a very good thermal conductivity and would ruin the thermal insulation quality.

It was the failure of the composite LH2 tank in the X-33 which eventually killed the project. One of the tanks cracked when it was cooled down with LH2. Lockheed Martin X-33 was an unmanned reusable spaceplane sub-scale technology demonstrator for the VentureStar with a height of 20 m (69 ft), a launch mass of 130000 kg, powered by 2J-2S Linear Aerospike engines with a thrust of 1.82 MN each. The VentureStar was planned to be a next-generation, commercially operated RLV. The X-33 would flight-test a range of technologies that NASA believed it needed for SSTO RLVs, such as metallic thermal protection systems, composite cryogenic fuel tanks for liquid hydrogen, the aerospike engine, autonomous (unmanned) flight control, rapid flight turn-around times through streamlined operations, and its lifting body aerodynamics. Most importantly, through the use of the lifting body shape, composite liquid fuel tanks, and the aerospike engine, NASA and Lockheed Martin hoped to test fly a craft that would demonstrate the viability of a SSTO design. An SSTO craft would not require external fuel tanks or boosters to reach low-earth orbit. Doing away with the need for “staging” with launch vehicles, such as with the Shuttle and the APOLLO rockets, would lead to an inherently more reliable and safer space launch vehicle. Testing of twin Linear Aerospike XRS-2200 engines, originally built for the X-33 program, was performed on 6 August 2001 at NASA’s Stennis Space Center, Mississippi.

The unmanned craft would have been launched vertically from a specially designed facility constructed on Edwards Air Force Base, and have landed horizontally on a runway at the end of its mission. Initial suborbital test flights were planned from Edwards AFB to Dugway Proving Grounds southwest of Salt Lake City, Utah. Once those test flights were completed, further flight tests would be conducted from Edwards AFB to Malmstrom AFB in Great Falls, Montana, to gather more complete data on aircraft heating and engine performance at higher speeds and altitudes. The X-33 was never intended to fly higher than 100 km altitude nor faster than 1/2 orbital velocity. Risky extrapolation would have been necessary to apply the results of successful tests (if these had ever occurred) to an orbital vehicle.

Construction of the prototype was some 85% assembled with 96% of the parts and the launch facility 100% complete when the program was canceled by NASA in 2001, after a long series of technical difficulties including flight instability and excess weight. In particular, the composite liquid hydrogen fuel tank failed during testing in November 1999. The tank was constructed of honeycomb composite walls and inter-

nal structures to lower its weight. A lighter tank was needed for the craft to demonstrate necessary technologies for SSTO operations. A hydrogen-fueled SSTO craft's mass fraction requires that the weight of the vehicle without fuel be 10% of the fully fueled weight. This would allow a vehicle to fly to low earth orbit without the need for the sort of external boosters and fuel tanks. NASA had invested \$912 million in the project before cancellation and Lockheed Martin a further \$357 million. Due to changes in the space launch business, including the challenges faced by companies such as Globalstar, Teledesic, and Iridium and the resulting drop in the number of anticipated commercial satellite launches per year, Lockheed Martin deemed that continuing development of the X-33 privately without government support would not be profitable.

## 4.4 Insulating Materials for Liquid Hydrogen Service

### 4.4.1 Selection of Insulating Methods

Although this book is dealing mostly with the chemistry of rocket propellants, some information is provided on the equipment needed to safely store, transport, and handle these propellants. Storage tanks, flight tanks, and pipes for liquid hydrogen must be properly insulated. There are at least four different methods for insulating LH<sub>2</sub> tanks and lines:

One can build double-walled tanks and lines with a vacuum jacket, double-walled tanks and lines with powder-filled and evacuated jackets, multiple foil insulation ("superinsulation") or one can insulate tanks and lines by surrounding them with rigid foam. The latter two types of insulating material can be applied either internally or externally.

Double-walled tanks with evacuated interspace are usually possible only with very small tanks because the atmospheric pressure exerts a substantial load on the evacuated walls. Internal supports to prevent the double-walled structure from collapsing are unwanted thermal paths and should be minimized. It is better to fill the void space between the two walls with a rigid powder with poor thermal conductivity, such as kieselguhr, diatomaceous earth, perlite [464] or Santocel<sup>®</sup>™. Santocel is a porous silica aerogel manufactured by the Monsanto Chemical Company. The grade used for thermal insulation (Santocel A) is a granular material.

If the small double-walled containers are made from glass, the surfaces are usually mirror-plated to reduce heat transfer by radiation ("Dewar flasks"); however, the reflectivity of the walls does not significantly reduce heat transfer when porous or fibrous insulation is used to fill the interstices. It has been suggested to add shiny, reflective aluminum flakes to the porous insulation to reduce heat transfer by radiation.

The pressure in the vacuum jacket (regardless if filled with porous materials or not) at room temperature should be below 0.01 Pa ( $10^{-4}$  mm Hg). It must be checked

from time to time and if necessary the jacket needs to be pumped down and re-sealed. Good tanks should hold their vacuum for at least 5 years.

Additional information on thermal insulation for liquid hydrogen tanks is to be found in the references listed in Table 41. This is a random collection of historical references relating to insulation for liquid hydrogen tanks, a good starting point for additional studies. The documents referenced here do not specify if the insulation is intended for stationary or flight tanks and what type of insulation (powder or multi-layer or foam) is being considered.

#### 4.4.2 Multi-Layer Insulation

The best thermal insulation can be achieved by alternating layers of corrugated (waffle-patterned, dimpled) poorly insulating (organic polymer) and highly reflective (mirrored metal foil), often called “superinsulation” [476]. This can be used both internally and externally. Aluminized Mylar<sup>®</sup> is highly reflective and well insulating but needs to be evacuated to remove all gas [477, 478]. It takes substantially more skilled labor work to install multi-layered insulation than filling a fluffy powder into the space between two tank walls. Therefore, multi-layer insulation is used mostly in flight vehicles and not in ground service installations.

There are other multi-layered insulating layer designs which are sealed against intrusion of air but not evacuated. Whatever gas is in the layer will condense and create a vacuum as long as the tank is cold. Such insulating layers can be used for upper stages which are exposed to aerodynamic heating while traversing the atmosphere [479, 480]. Their insulating quality is not as good as that of evacuated layers but they only weigh a fraction of evacuated double-layer systems.

The outer surface of tank installations should have high reflectivity, in particular in the infrared regime, in order to minimize heat absorption in bright sunshine. Polished aluminum surfaces have good reflectivity.

An improvement of external insulation in SATURN-V SII second stage was a multi-layer insulation (MLI) in which aluminized Mylar<sup>®</sup> alternated with honeycomb profiles from phenolic resin [481]. The inner honeycomb cells were hermetically sealed, and the outer layers were purged with cold helium which was supposed to prevent air intrusion. The SIVB third stage had internal insulation. This insulating layer weighed  $253 \text{ g/m}^2$  and had a thermal conductivity of  $0.043 \text{ W m}^{-1} \text{K}^{-1}$  ( $0.025 \text{ BTU h}^{-1} \text{ft}^{-1} \text{°F}^{-1}$ ).

A subscale LH2 storage facility test article for instrumented steady-state and transient thermal tests was designed and a two-stage gaseous helium refrigerator was integrated with the test article and used to reduce boil-off and/or decrease the time required between passive test configuration steady-state conditions. Predictions of a computer program for calculation of space-based liquid hydrogen storage boil-off losses from multi-layer insulated tanks were conservative and consistently high compared to actual measurements [482].

#### 4.4.3 Foam Insulation

The last of the four methods listed at the introduction to this section, applying an external insulation of plastic organic (combustible) foam, was initially considered inappropriate for liquid hydrogen service, because it was feared that air would be sucked into the foam (“cryopumping”) and continue to condense, saturating it with liquid oxygen (which creates an explosive hazard) [483, 484].

The problems of safety associated with the design of a casing enclosing hydrogen process equipment at cryogenic temperatures are somewhat more complex than those of a typical oxygen-nitrogen plant, and several additional factors must be considered. It is necessary to keep air out of the insulation and provide a safe means for venting process fluids from the casing in the event of a large leak. An inert blanketing atmosphere such as nitrogen or helium may have to be kept in the casing, the gas would be selected depending on the process operating temperatures [485]. If the foam layer is not hermetically sealed, the condensation of air on the outside of the tank causes additional evaporation losses [480, 486]. The intrusion of air could be avoided if the foam was continuously purged with cold helium gas, which would be an added complication. In a launch vehicle, if the hydrogen level can be maintained during countdown by topping off the tank through the umbilical until a few minutes before launch, an external foam insulation may be sufficient and internal insulation is not required [487, 488].

History, in particular the history of the development of the external tank of the Space Shuttle, has shown that external foam insulations can provide good thermal insulation, even if the mechanical integrity of the foam during the boost phase leaves a lot to be desired and the impact of breakaway chunks of foam onto the leading edge of Space Shuttle Columbia wings led to the second Space Shuttle disaster with a loss of spacecraft and crew.

Selecting the right insulating material is a matter of optimizing thermal conductivity versus weight. Some insulating materials may also have sufficient rigidity that they support the tank wall against buckling such that the tank wall can be made a bit thinner [489]. The other optimization is dependent on the decision to use internal or external insulation. Internal insulation has the advantage that the insulating layer is not penetrated by support struts that act as undesirable heat leakage paths.

The SATURN S-IV and S-IVB upper stages hydrogen tanks employed internal insulation [490]. It was assembled from contoured foam tiles, which were later covered by a fiber glass-reinforced layer of epoxy resin and sealed with six layers of polyurethane sealant. In spite of this sealant, there were indications that hydrogen diffused into the insulating layer and caused some unexpected evaporation losses. If the S-IVB stage had evolved into a true interplanetary stage with long coasting periods between burns, such as doing a lunar orbit insertion burn, then it would have to be wrapped with additional layers of superinsulation [491].

A quasi steady-state model for the comparison of the thermal performances of foam and multi-layer insulation for a cryogenic liquid hydrogen tank during the ascent and on-orbit phase calculated the corresponding parameters within the temperature range from 55 to 700 K, and pressure range between  $10^{-6}$  and  $10^5$  Pa during the whole process [492]. The model was validated by the experimental results and turned out to have good prediction accuracy. Thermal resistance distributions of foam and multi-layer insulation were compared in detail, and their contributions to reduce the heat leakage and vaporization losses were analyzed and would help to optimize the future design of foam/MLI for cryogenic storage tanks.

## 4.5 Other Materials for Handling of Liquid Hydrogen

### 4.5.1 Sealants for Liquid Hydrogen Service

As sealants for gaskets and valve seats there are only few elastomers that are still elastic at the very, very low temperature of liquid hydrogen. Teflon has been used because no other material was available, but even Teflon becomes brittle at 20 K.

The search for polymers suitable for low-temperature service continued for a long time [493]. In many cases one will make provision for multiple seals, one at the cold temperature and a secondary seal at a higher temperature closer to the outside.

Extreme conditions were encountered in the KIWI, NERVA, and ROVER nuclear thermal rockets. At the transition between the reactor and the expansion nozzle the flanges were tightened with metal seals [494]. Diverse materials were tested as adhesives, foils, thermal insulation, and electrical wire insulation that had to withstand hot/cold cycles, nuclear radiation, and the vacuum of space in nuclear thermal rockets, although they never left the ground [495].

### 4.5.2 Adhesives for Liquid Hydrogen Service

Fifteen different adhesives were evaluated for their ability to provide a hermetic seal in lap joints between thin metallic foils and plastic films in the presence of gaseous and liquid hydrogen [496]. The lap joints were tested in a manner that provided a pressure difference of 20 psi through the adhesive bond line but did not subject the joint to any

mechanical stresses or loads. Each adhesive was tested at room, liquid nitrogen and liquid hydrogen temperatures. The adhesives tested were commercially available and included epoxy-polyamines, nylon-filled epoxies, urethanes, polyesters, and rubber-based adhesives. In general, the most satisfactory adhesives system for sealing aluminum to aluminum, Mylar to Mylar, and Mylar to aluminum at cryogenic temperatures were the epoxies.

#### **4.5.3 Lubricants for Liquid Hydrogen Service**

Most commonly used lubricants are useless at the low temperature of liquid hydrogen because they freeze solid. Dry bearings made from graphite or graphite-filled polymer-impregnated composites which can usually be used over a wide temperature range begin to fail at liquid hydrogen temperatures because friction increases significantly at low temperatures.

## **5 Handling of Liquid Hydrogen**

The handling of liquid hydrogen at rocket test stands and at launch sites requires a special set of precautions that exceed those required for other propellants. For many launch sites around the world, handling of liquid hydrogen has already become routine. The literature referenced here reflect some of the learning the early propellant handlers had to go through when liquid hydrogen was first used as a rocket propellant during the past century. Most of the following publications are only a historical summary and have been superseded by more modern handling and crew training manuals. Additional information on safe handling and potential hazards of liquid hydrogen can be found in the publications listed in Table 44. This listing was not kept up to date but is a good start for further study.

As the most important precaution, liquid hydrogen should not be allowed to come in contact with air, because oxygen and nitrogen will condense into it and form explosive mixtures. Whereas transfer lines in ground service equipment which are in use for only short periods of time sometimes remain without insulation where liquid oxygen or liquid nitrogen has to be transferred, corresponding lines for liquid hydrogen are always insulated and sealed from the surroundings to prevent condensation of air and to reduce hydrogen evaporative losses during cooldown and operations. One of the first commercial rocket engine test sites for LOX/LH<sub>2</sub> engines was the test site of Pratt & Whitney in West Palm Beach, FL, where much experience with the handling of liquid hydrogen was gained [524]. See also [525].

### 5.1 Liquid Hydrogen Logistics

Liquid hydrogen (and liquid oxygen) is a volatile commodity and procurement and demand forecast require careful planning [526]. One of the trade-offs is between production plant capacity, separation distance between source and point of end use and storage capacity.

As of 2002, tank trucks hauled more than 804000 kg of liquid hydrogen fuel about 965 km from New Orleans to NASA KSC for every Shuttle launch. Each time the Shuttle was fueled, about 260000 kg of hydrogen would burn off in a flare stack or evaporate. NASA had to bring in a third more fuel than the Shuttle actually used. In 2002, NASA

Glenn Research Center (GRC) awarded an 8M\$ contract to a group of Florida universities to study hydrogen logistics.

## 5.2 Storage of Liquid Hydrogen

The best summary of information on liquid hydrogen storage and transmission is now available in [527]. This book contains a photo of a very large liquid hydrogen storage tank (Figure 56). See also [528].

### 5.3 Design Considerations for Liquid Hydrogen Storage Facilities

#### 5.3.1 Regulatory Requirements for Liquid Hydrogen Storage Facilities

Various government agencies and commercial organizations have issued regulations, industry standards and recommendations for the safe storage of liquid hydrogen. Storage and transportation of hydrogen within the US is governed by 29 CFR-1910.103 Hydrogen. § 1910.103, paragraph (c), pages 229–237 of this section applies to the installation of liquefied hydrogen systems on consumer premises. 14 CFR, Chapter III – Commercial Space Transportation, Federal Aviation Administration, Department of Transportation, Part 420 – License to Operate a Launch Site; Subpart D – Responsibilities of a Licensee; Section § 420.66 contains separation distance requirements for storage of liquid hydrogen and any incompatible energetic liquids stored within an intraline distance.

DoD 6055.09-STD [529] sets requirements for siting LH2 storage and piping in relation to facilities and other propellants and chemical storage and for personnel monitoring. Although DoD 6055.9-STD does not address piping design, construction, or testing, it is recommended by this guide that all vessel and piping systems for propellant hydrogen service be designed, constructed, and tested in accordance with ASME B31.3 and Compressed Gas Association (CGA) G-5.4. NASA Standard, “Safety Standard for Explosives, Propellants and Pyrotechnics.”

Liquid hydrogen is in the DoD Storage Hazard Class 2.1 (LB). Group LB includes “Energetic liquids that are readily combustible when exposed to, or ignited in the presence of an oxidizing agent, but that are not strong reducing agents.” Table C9.T22 establishes Quantity-Distance (QD) Criteria for Liquid Hydrogen and Bulk Quantities of Hydrazines.

NASA-STD-8719.12A [530] incorporates the requirements from DoD 6055.9. Table 5.33 is identical with Table C9.T22 of DoD 6055.09-STD.

NFPA 50B describes “Liquefied Hydrogen Systems at Consumer Sites.” The QD requirements of NFPA 50A and 50B are based on the concept that the effects of fire, explosion, and detonation can be reduced to tolerable levels if the source of the hazard is kept far enough from people and other facilities. The NFPA hazard diamond for liquid hydrogen has a 3 for health hazard (frostbite) and a 4 (worst possible) for fire hazard (Figure 57).

#### 5.3.2 Design of Liquid Hydrogen Storage Tanks

In order to minimize evaporation losses, the thermal insulations in stationary tanks are usually thicker and heavier than those in flight vehicles. Evaporation losses are a function of the surface to volume ratio. This ratio is the most favorable for a sphere. For this reason large hydrogen storage tanks are often designed and built in spherical shapes.

Figure 57: NFPA hazard diamond for liquid hydrogen

Some of the observations and recommendations on the storage of hydrogen reported here apply equally well to storage any of cryogenic liquid, including liquid helium or liquid oxygen. We are discussing this topic here in more detail for liquid hydrogen because much of the new cryogenic technology was developed specifically for this rocket propellant. There have been many conferences devoted specifically to the cryogenic technology for liquid hydrogen.

Hydrogen storage tanks should be kept under a slight overpressure to prevent intrusion of air. The evaporating hydrogen escapes through a pressure relief valve and is fed into a manifold that is constantly purged with nitrogen. The manifold leads away from the tank and in a safe distance into a vent and flare stack. The top of the vent stack carries a check valve and explosion barrier (metal foam, wire mesh) to prevent flashback of the combustion into the vent duct [531, 532].

Liquid hydrogen storage tanks, like all hazardous chemical storage areas, are usually surrounded by a berm and a catch basin that is intended to collect any leakage and restrict its overflow and travel to adjacent storage areas.

In order to avoid fires, all electrical installations must be spark-proof and must be grounded. Electrostatic charges are a serious threat when pumping non-conductive liquids.

Warm hydrogen gas rises in air and may collect underneath roofs and awnings, forming explosive mixtures. Hydrogen storage or test areas that are covered must be well ventilated. See also [533].

#### 5.4 Evaporation Losses from Stationary Liquid Hydrogen Storage Tanks

Evaporation losses are higher from cylindrical containers than from spherical containers with equal volume and same construction and thermal insulation. In spite of this disadvantage there are many cylindrical tanks in use for liquid hydrogen, mostly for tank cars and in rockets, where not only the surface to volume ratio, but also the

cross-sectional area is important to fit under bridges and through tunnels and have a small cross-section to reduce aerodynamic drag in flight.

#### 5.4.1 Influence of ortho-para Conversion on Evaporation Losses

The rate of evaporation losses during storage depends on the completeness of the conversion of orthohydrogen to parahydrogen during the liquefaction which should be as close to the equilibrium composition as possible. Figure 58 illustrates the evaporation losses as a function of ortho to para conversion and time. In order to prevent excessive evaporation losses during storage, one will want to achieve as complete as possible conversion of the room temperature equilibrium composition hydrogen to parahydrogen.

**Figure 58:** Evaporation losses of liquid hydrogen due to ortho-para conversion as a function of initial composition. (Reproduced and modified from [41].)

The evaporation of liquid hydrogen caused by the heat of reaction of the ortho-para conversion has been measured as a function of the orthohydrogen concentration [534].  $o \rightarrow p$  and  $p \rightarrow o$  conversion rates were measured within the entire range of existence of the liquid phase and in the gas for temperatures up to 120 K and pressures up to 700 bar [407, 535, 536]. All measurements were made under careful exclusion of catalytic (paramagnetic) materials and the containers were only glass or beryllium. Tests with different surface: volume ratios in the beryllium containers gave identical results, verifying that there was no surface catalysis of the conversion. Measurements were made of natural ortho-para conversion rates in  $H_2$  in a wide

range of fluid states: in the liquid at temperatures 16.65, 20.4, 24.15, 28.06, and 32.15 K and pressures up to 500 bar (densities from 0.05 to 0.09 g/cm<sup>3</sup>) and in the gas at temperatures 40, 51.15, 77.5, 90, and 120 K and pressures from 20 to 700 bar (densities from 0.019 to 0.085 g/cm<sup>3</sup>). The low-temperature ( $T > 4.2$  K) ortho-to-para conversion in hydrogen occurs according to the following equation, established in experiments on liquid and solid H<sub>2</sub>

$$\frac{dc}{dt} = -kc^2 + k'c(1-c)$$

where  $k$  and  $k'$  are the  $o \rightarrow p$  and  $p \rightarrow o$  conversion constants and  $c$  is the orthohydrogen concentration. The conversion constants are calculated from

$$k = \frac{1}{ta} \ln \frac{(c_f - c_e)c_i}{(c_i - c_e)c_f} \quad a = \frac{k'}{k} = \frac{c_e}{1 - c_e}$$

where  $k$  is the kinetic constant in h<sup>-1</sup>,  $c_i$  is the initial concentration,  $c_f$  is the final concentration, and  $c_e$  is the equilibrium concentration of orthohydrogen. The interpolation formula for the entire range of fluid phases has the form

$$k = A(T)\rho + C(T)\rho^p$$

where  $p = 3.6$ ,  $k$  is in units 10<sup>-3</sup> h<sup>-1</sup>, the temperature in K, and  $\rho$  is in g/cm<sup>3</sup>, then  $A(T) = A_0 T^n$ ,  $A_0 = 18.2 \pm 1.6$ ;  $n = 0.56 \pm 0.02$  and  $C(T) = 5 \times 10^4 (C_0 + DT^{-m})$  with  $C_0 = 0.77 \pm 0.03$ ;  $D = 921 \pm 91$ ;  $m = 2.5 \pm 0.2$ . Figure 59 shows the  $o \rightarrow p$  conversion constant

**Figure 59:**  $o \rightarrow p$  Conversion constant of liquid hydrogen as a function of density. (Republished and modified from [536], with permission of ©1997 Springer New York LLC; permission conveyed through Copyright Clearance Center, Inc.)

**Figure 60:**  $o \rightarrow p$  Conversion constant of gaseous hydrogen as a function of density. (Republished and modified from [536], with permission of ©1997 Springer New York LLC; permission conveyed through Copyright Clearance Center, Inc.)

of liquid hydrogen as a function of the density with the temperature as the auxiliary parameter. Figure 60 shows a similar graph for the  $o \rightarrow p$  conversion constant of gaseous hydrogen as a function of the density with the temperature as the auxiliary parameter.

A tank storing liquid hydrogen at 20 K and containing only 90% parahydrogen instead of the equilibrium concentration will lose an additional 0.25% of its content per day, in addition to the loss due to unavoidable heat leakage through the walls of the container. In the presence of catalysts, traces of oxygen or steel, the conversion and evaporation loss may occur even faster [4].

Evaporation losses from storage tanks are size dependent. Larger tanks are more economical for long-term storage. Very large tanks containing 1900000 L have demonstrated evaporation losses of only 0.06%/day in comparison to 0.24%/day in a 94000-L container. It is more economical to store liquid hydrogen in one large tank than in several small ones.

#### 5.4.2 Active Cooling to Prevent Evaporation Losses

It is possible to condense the evaporating hydrogen and return it to the storage volume if it is not permissible to vent the boil-off. The extra energy expenditure and the capital cost of the extra installation will have to be subject to an economic analysis [537]. The benefit of recondensation depends on the tank size. In many cases it will be less expensive to just purchase more liquid hydrogen and make an allowance for evaporation losses.

Evaporation losses occurring during liquid hydrogen transfer operations to cool down the lines and the receiving vessels are much faster and usually cannot be captured by recondensation or temporarily storing the large amount of gas in a gasometer for later use and reliquefaction at a slower rate [538]. Each storage facility will have to have a vent stack with a flare to handle these high flow conditions. Sometimes it is possible to precool the equipment by a recirculating flow of cold helium gas. That would reduce the vaporization losses when the tank is first filled with hydrogen. Precooling the liquid hydrogen to near slush formation temperature would also reduce the vaporization losses during cooldown of the equipment.

### 5.5 Hydrogen Flare Stacks

A design guide for hydrogen vent systems includes pressure relief valves and other safety devices [539]. The nitrogen purge of the vent duct should be turned off before venting cold hydrogen gas, otherwise nitrogen might solidify in the duct and clog the vent duct. If the vented hydrogen is always very cold, the vent duct may have to be purged with helium instead of nitrogen.

This publication presents design guidelines for hydrogen vent systems used in gaseous and liquid hydrogen systems at user sites and provides recommendations for safe operation of these vents. It begins at the discharge port of safety devices and other components that control the release of hydrogen and ends at the point where hydrogen concentration in the atmosphere is below the lower flammable limits. It also provides information on the production, transportation, handling, and storage of compressed hydrogen, cryogenic liquid hydrogen, and related products.

Boil-off from liquid hydrogen storage tanks or gas released during chilldown of equipment has to be collected in a duct and fed to a flare stack for safe disposal. The duct manifold leads away from the gas source and at a safe distance leads into a vent and flare stack. The top of the vent stack carries a check valve and explosion barrier (metal foam, wire mesh) as flashback arrestors [531, 532]. Under certain adverse conditions, explosions may occur in flare stacks if air can enter before the flare is ignited [540]. It is best to keep the pilot flame burning all the time to prevent this from happening.

Experiments showed that ambient air may enter the top of a hydrogen flare stack and cause problems when the hydrogen flowrate is too low [541, 542]. Diffusion flames burning in air on a wide, upright pipe (stack) and fed with slow, upward flows of buoyant gas may induce a downward flow of air along the interior walls of the pipe that can support combustion within the pipe. Predicted flame dip limits agreed roughly with experimental values determined on 6, 12 and 18-in. diameter stacks and increased with increasing stack diameter. Measurements were made of the limiting flow at which a hydrogen diffusion flame blows out in still air. Burning rates of large hydrogen diffusion flames ranging from about 1 to 30 cm/s (0.03–1 ft/s) were used to predict approximate flame heights on flare stacks (Figure 61).

There is concern that strong crosswinds may snuff out the flame on top of the flare stack [543]. Crosswinds do not strip significant amounts of unburned hydrogen from its diffusion flame. Flames held on bluff bodies in ducts owe their stability to the recirculation zone behind the flame holder. This zone may be thought of as a pilot flame that keeps the main flame established as long as it is able to ignite the mixture flowing

**Figure 61:** Dip limits of hydrogen diffusion flames into flare stack. (Reproduced and modified from [542].)

past. Blow-off occurs if the main stream flows so fast that sustained ignition cannot be achieved. The flow velocity at which this condition arises depends on the size and shape of the flame holder as well as on the temperature, pressure, and composition of the incoming mixture. Water-cooled flare stacks are not likely to be damaged when the flame is blown back into them by opposing winds.

## 5.6 Examples of Liquid Hydrogen Storage Facilities

### 5.6.1 USA

As of 1968, the largest tank built in the western world was a spherical tank containing 2650000 L of liquid hydrogen. The inner sphere with a diameter of 17.4 m was made from Al-5083, the outer shell was from steel. Smaller containers were made from titanium alloys [425].

At the KIWI test site of the Atomic Energy Commission there were initially two liquid hydrogen tanks with 190000 L contents, each of which could be pressurized to 6.8 atm [9, 10]. The thermal insulation consisted of a 91-cm thick layer of perlite. The evaporation losses ran at only 0.2%/day.

Later the AEC started testing a larger nuclear thermal rocket engine attached to the PHOEBUS nuclear fission reactor which delivered 5000 MW thermal. This effort required an increase of the liquid hydrogen storage capacity by a factor of 10. Toward the end of the program there were two spherical tanks with a net volume of 1900000 L each (allowing for 10% ullage) at the test site. The larger tanks were also insulated with perlite and could be pressurized to 7 atm overpressure.

While the test duration during KIWI-A testing was limited to 500 s (a supply of 380000 L consumed at a flow rate of 2700 L/min.), later tests with a flow rate of 130000 L/min. were extended to 2000 s. The suction line had an internal diameter of 40 cm and the feed line had a diameter of 25 cm and was rated for a feed pressure of 135 atm gauge.

In the foreground in front of the Space Shuttle launch pad is the liquid hydrogen storage tank used during the Space Shuttle era (Figure 62). In 2018 NASA started construction of a new spherical liquid hydrogen storage tank at KSC with a capacity of 4730 m<sup>3</sup> (1.25 million gallons) and a diameter of 25 m. Instead of evacuated Perlite insulation, the new tank will have evacuated glass bubble insulation. Liquid hydrogen losses through boil-off can be reduced by as much as 46% by using the different insulation fill material. The new tank will have a refrigeration system allowing control of the fluid inside the storage tanks. This approach provides direct removal of heat energy using an integrated heat exchanger together with a cryogenic refrigeration system.

**Figure 62:** Liquid Hydrogen Ground Storage Tank at NASA Kennedy Space Center. NASA Photo No: KSC-05pd-1569 (14 July 2005).

### 5.7 Stratification Problems with Liquid Hydrogen

Heat leak to cryogenic propellant tank causes buoyancy-driven liquid stratification, resulting in formation of a warm liquid layer at the top of the liquid free surface. This warm stratum may be further heated by the admission of warm pressurant gas for tank pressurization during engine operation. Since stratified layer temperature has a direct bearing on the cavitation-free operation of turbo pumps integrated into cryogenic rocket engines, it is necessary to model the thermal stratification for predicting stratified layer temperature and mass of stratified liquid in the tank at the end of engine operation. These inputs are required for estimating the minimum pressure to be maintained by the tank pressurization system and for the net positive suction head. If a tank containing initially well-mixed liquid hydrogen (or any other cryogenic fluid) is pressurized, as is often done for pressure-feeding or to prevent cavitation on the suction side of a pump, the boiling and mixing stops, and the liquid comes to rest for a while. If the heat influx to the tank comes uniformly from all sides, the warmer fluid will rise and collect in the top layer while the colder fluid remains at the bottom. The pressure in a stratified tank will rise faster than in a well-mixed tank. This stratifica-

tion is highly undesirable and can cause several types of operational problems. This problem has been extensively described and discussed in the cryogenic engineering literature, see the list of publications in Table 45.

**Table 45:** List of publications on stratification in liquid hydrogen.

One way to avoid stratification is to allow heat leakage through support structures mainly at the bottom of the tank. In a gravity field, the upwelling and convection would then assure continued mixing even after pressurization. This works only in a gravitational field and not in outer space. Another method is the installation of a chimney in the tank which facilitates circulation by convection; however, in a zero-g environment all anti-stratification methods depending on convection will lose their effectiveness.

An experimental investigation was made to determine the behavior of liquid hydrogen in a 473 L (125 gallon) scale model of a propellant tank subjected to a range of wall heat flux from 13.6 to 93 W/m<sup>2</sup> (0.0012–0.0082 BTU ft<sup>-2</sup> s<sup>-1</sup>) and a range of bottom heat flux from 5.7 to 111 W/m<sup>2</sup> (0.0005–0.0098 BTU ft<sup>-2</sup> s<sup>-1</sup>) while discharging from the tank at a rate of 18 g/s (0.04 lb/s) under a constant tank pressure of about 202 kPa (2 atm) [555]. Increasing temperature stratification in the liquid was encountered with increasing wall heat flux. A decrease in stratification was experienced with increasing bottom heat flux. An available analysis partially predicted the increase in temperature stratification.

A thermal model was developed for a foam-insulated LH2 tank subjected to heat leak and pressurization with hydrogen gas at 200 K during liquid outflow at 38 L/s for engine operation [556]. The model considers buoyancy flow in a free-convection boundary layer caused by heat flux from the tank wall and energy transfer from warm pressurant gas to predict temperature of the liquid stratum and the mass of stratified liquid in a 30 m<sup>3</sup> tank at the end of engine operation in a cryogenic upper stage qualification stationary ground test firing.

Cryogenic liquids stored in a tank generally show different thermodynamic behaviors because of the heat ingress from the outside. Compared with those predicted by the homogeneous model, experimental results indicated different behaviors because of thermal stratification. The results particularly showed that thermal stratification is highly correlated with the thermal aspect ratio [557]. The top layer results in faster pressure increases, which is in contrast with the result predicted by the homogeneous model. The boil-off gas rate generated is significantly less than that predicted by the general calculation in the homogeneous model even if much boil-off gas is generated in the early stage in a system with a warmer top layer. It was shown that the thermodynamic behaviors resulting from thermal stratification are significantly different from those predicted by the homogeneous model.

For a liquid hydrogen tank in zero-g, stratification can be destratified by spinning the spacecraft. A method was presented for determining the onset of a thermally induced convective mixing motion in a model of a cylindrical space-storage tank subjected to a constant heat flux at its outer boundary. The model simulated a completely filled liquid cryogen tank with shear-free ends rotating in a low-gravity environment [558].

## 5.8 Self-Pressurization of Locked-up Liquid Hydrogen Tanks

The pressure rise rate in a locked-up, quiescent, stratified tank is different from that of a well-mixed tank and depends on the presence or absence of gravity [559–560]. Self-pressurization of liquid hydrogen tanks under conditions of reduced gravity is discussed at the end of this section.

The rate of pressure increase following the closure of the vent line in a tank and the pressurization gas requirements depend significantly on the amount of stratification in the tank [549, 550]. The temperature difference between the top layer and the bottom layer can amount to several degrees K. The temperature fluctuations of the propellant taken from the tank cause irregular deviations in the other physical properties of the propellant as it wends its way through the system. The properties will vary depending on which layer of the liquid the propellant was taken from.

The self-pressurization of a tank following closure of the vent line will occur faster with stratification than with a uniformly mixed liquid. Stratification is closely related to the rate of self-pressurization of liquid hydrogen in a tank once the vent is closed and the tank is allowed to come up to a safe operating pressure without adding any pressurant gas [561].

A non-venting 23-cm (9-in.) diameter spherical tank partially filled with liquid hydrogen was subjected to 4 uniformly heated self-pressurization tests [562]. These tests were conducted with various combinations of liquid filling levels, heat-transfer rates and either top heating, bottom heating or uniform heating.

A non-venting 56-cm (22-in.) diameter spherical tank partially filled with liquid hydrogen was subjected to 4 uniformly heated self-pressurization tests [563]. These tests were conducted with various combinations of liquid filling levels (approximately 30–80% by volume) and heat transfer rates (approximately  $53\text{--}202\text{ W/m}^2 = 17\text{--}64\text{ BTU h}^{-1}\text{ ft}^{-2}$ ). These data were compared with data from a similar study performed on a 23-cm (9-in.) diameter, uniformly heated, spherical tank and with the self-pressurization of a 189000L (50000 gallon) spherical liquid-hydrogen storage tank. The data from the 23-cm (9-in.) and 56-cm (22-in.) diameter spherical tank tests verified the analysis which predicted that the effect of size on self-pressurization of hydrogen tankage can be expressed as a simple geometric relation involving the heat added per unit volume. The conclusion was supported by the fact that the pressure data, plotted as a function of heat added per unit volume, fell within a narrow band. The pressure rise rate increased almost linearly with increasing heat transfer rate; however, as the heat transfer rate was increased, the contents of the 23-cm (9-in.) tank became slightly less homogeneous while the contents of the 56-cm (22-in.) tank remained essentially the same. This difference was attributed to the thicker wall of the 22-inch (56-cm) tank which absorbed a larger proportion of the incoming energy at the higher heat transfer rates and caused a change to more bottom heating. For both the 23-cm (9-in.) and 56-cm (22-in.) tanks the pressure rise rate was only slightly affected by varying the percent filling with a trend toward increasing pressure rise rates at higher fillings. The 189000L (50000 gallon) spherical liquid-hydrogen storage tank described in earlier work had a much greater rate of pressure rise, when compared with the homogeneous analysis, than either of the smaller tanks. This difference was attributed to a different mode of heat transfer in the liquid. At the low heat fluxes encountered in the earlier experiment ( $1.9\text{ W/m}^2 = 0.6\text{ BTU h}^{-1}\text{ ft}^{-2}$ ), heat was transported in the liquid by laminar natural convection rather than by turbulent convection as was the case for the tests on the smaller tanks so that larger temperature gradients and non-homogeneous conditions resulted.

A computer program was developed for calculating the thermal stratification and the associated self-pressurization of a closed liquid hydrogen tank [564]. The historical FORTRAN-IV programming language was used and runs were made on IBM 360/65 and CDC 3600 computers. Comparisons were made between the program calculations and test results from both ground and orbital coast tests of a CENTAUR upper stage.

Self-pressurization and thermal stratification tests of a  $4.89\text{-m}^3$  liquid hydrogen storage tank subjected to low-heat flux ( $0.35, 2.0, \text{ and } 3.5\text{ W/m}^2$ ) under normal gravity conditions were performed at fill levels of 83–84% (by volume) [565]. The LH2 tank was representative of future spacecraft tankage, having a low mass-to-volume ratio and high performance multi-layer thermal insulation. Results showed that the pressure rise rate and thermal stratification increased with increasing heat flux. At the lowest heat flux, the pressure rise rate was comparable to the homogeneous rate, while at the highest heat flux, the rate was more than three times the homogeneous rate. It was found that initial conditions had a significant impact on the initial pressure rise rate.

The quasi-steady pressure rise rates were nearly independent of the initial condition after an initial transient period had passed.

Tests of self-pressurization and thermal stratification of a  $4.89\text{-m}^3$  liquid hydrogen storage tank subjected to low heat flux ( $2.0$  and  $3.5\text{ W/m}^2$ ) in normal gravity, which was representative of future spacecraft tankage, having a low mass to volume ratio and high performance multi-layer thermal insulation, were performed at fill levels of 29 and 49% (by volume) and complement previous tests at 83% fill [566]. As the heat flux increased, the pressure rise rate at each fill level exceeded the homogeneous rate by an increasing ratio. This ratio did not exceed a value of 2. The slowest pressure rise rate was observed for the 49% fill level at both heat fluxes. This result was attributed to the oblate spheroidal tank geometry which introduces the variables of wetted wall area, liquid-vapor interfacial area, and ratio of side wall to bottom heating as a function of fill level or liquid depth. Initial tank thermal conditions were found to affect the initial pressure rise rate.

Three different pressure rise models were employed to calculate the self-pressurization and boil-off rates in cryogenic vessels [567]. These were a homogeneous model, a surface evaporation model and a thermal stratification model. The first two models were based on the assumption that no temperature gradients exist in the tank, while the thermal stratification model takes the temperature distribution into account. Employing the thermal stratification model, temperature gradients and their effect on the pressure rise rates in liquid hydrogen tanks were analyzed.

The rate of vaporization losses in a cryogenic tank has important design consequences for propellant and LH2 support systems planned for long duration space missions. The amount of liquid in the tank and the heat leak rate and distribution can all have an effect on the pressurization rate. A model fluid experiment was performed in normal gravity [568]. Experimental results showed that after undergoing an initial transient, the tank pressure rose at a uniform rate. The thermal inertia of the tank wall cannot be neglected and a thermodynamic model of the wall effects was developed. Comparisons showed good agreement between the pressurization rate predicted by the thermodynamic model and the obtained pressurization rate when the heat was added to the liquid but discrepancies arose when heat was added directly to the vapor.

At stationary conditions the pressurizing period is expected to be shorter because the contents of the tank will slowly stratify, so that the heat capacity of the stored fluid cannot be used completely [569]. From a thermodynamic point of view, an isochore change of state takes place and the heat flux into the vessel rises the internal energy of the fluid.

The effect of surface evaporation on stratification in large liquid hydrogen storage tanks of different aspect ratios was represented by a homogeneous two-phase model and the continuity, momentum and energy equations for the two phases were solved [570]. Evaporation at the liquid-vapor interface was incorporated through a source term for mass transfer. The amount of stratification was seen to progressively

increase as the aspect ratio of the tanks increases; however, the surface evaporation brings down the differences in the amount of stratification with changes of aspect ratio. The model gave predictions for stratification in the pre-evaporation and evaporation phases.

In optimizing the design of cryogenic storage facilities for future in-orbit or on-surface applications, the boil-off and the self-pressurization rates must be accurately predicted for different  $g$ -levels and for a variety of heat loads and distributions. A two-phase CFD model was developed that described the self-pressurization behavior of a flight weight partially full LH2 tank in normal gravity [571]. Existing experimental data at different fill levels were used to assess the predictive capability of the model. The model's predictions indicated good agreement with the experimentally measured pressure histories. Small deviations were observed for the median fill level cases where it was suggested that a non-uniform heat load may be the source of this discrepancy.

Cryogenic vaporization, caused by heat leakage into the tank from the surrounding environment, is one of the main causes of mass loss and leads to self-pressurization of the storage tanks. Many publications on self-pressurization and stratification of cryogenic tanks mainly focused on the convection and surface evaporation influences. Because large superheats increase the likelihood of evaporation in the liquid, the evaporation and its effect on vapor pressure under microgravity were studied and the effects of reduced gravity, contact angle of the vapor bubble, and surface tension were investigated [572]. The computations were carried out by using the CFD software package, ANSYS Fluent, and an in-house developed code to calculate the source term associated with the phase change. A coupled level set and the volume-of-fluid method was used to solve a single set of conservation equations for the whole domain and the interface between the two phases was tracked or captured. A heat and mass transfer model was implemented into the Fluent code for solving problems involving evaporation or condensation. Results showed that tiny vapor regions caused by the evaporation process change the pressure rise. Vortices were observed due to the vapor dynamics.

The commercially available computer program ANSYS Fluent was again used for simulation and analysis of self-pressurization of a flight weight, cryogenic, liquid hydrogen tank in 1- $g$  and the results were compared with experimental data, in particular, pressure evolution and temperature measurements at a 3-D set of sensors [573]. The simulations can be analyzed to identify and quantify heat flows in the tank. Heat flows change over time and influence the self-pressurization process. The initial rate of self-pressurization is sensitive to the initial temperature profile near the interface. Uncertainty in saturation pressure data and the accuracy of experimental measurements complicated the simulation of self-pressurization. The cryogenic hydrogen tank simulated is the same as that used in the K-Site experiment performed at the Cryogenic Propellant Tank Facility at NASA Plumbrook research center in the 1990s. This large, flight weight, 2219 aluminum tank with MLI insulation was tested in vacuum condi-

tions at 350 K shroud temperature and 1-g. The 2.2-m diameter tank consisted of two elliptical domes and a very small barrel section. Although the tank was tested for self-pressurization at 29, 49, and 83% fill levels, the simulations were focused on the 49% fill level.

A transient analytical, multi-phase, thermodynamic model of foam insulated liquid hydrogen tanks was developed to explain the effect of insulation thickness on the evolution of tank pressure and liquid thermal stratification [574]. The model was validated with experimental data reported in the literature. Analyses were carried out for pressurization considering two scenarios: first case with tank vent port closed after pressurization to study the pressure evolution and the second case for a constant tank pressure of 3.0 bar to study the growth of liquid thermal stratification. Both cases were investigated for different tank insulation thicknesses of 10, 20, 30, and 40 mm, and with a pressurization gas temperature of 50 K. Effects of variations in ambient atmospheric wind velocity and presence of solar flux on an asymmetric self-pressurization profile of the tank were also analyzed. The calculation showed that the reduction in insulation thickness would lead to an increase in stratified mass. The calculations predicted a significant increase in pressure rise when the tank was insulated with thinner insulation thickness. The rate of self-pressurization is of course related to the level of pre-pressurization that existed at the moment when the tank was locked up [575].

For studying the self-pressurization of locked-up liquid hydrogen tanks in reduced gravity, at first a series of self-pressurization tests was conducted to determine the thermodynamic history of a 23-cm- (9-in.-) diameter sphere under normal gravity conditions. Various combinations of the variables: percent liquid filling, heat-transfer rate, and heat-transfer distribution were studied. Next the tests were repeated at reduced gravities [576]. The rate of pressure rise in the hydrogen container was lower under reduced-gravity conditions than under normal gravity conditions because of the increase in the liquid-wetted wall area and the increased boiling. The location of the sources of heat input relative to the hydrogen liquid and vapor was the most important factor in determining the rate of pressure rise. Self-pressurization of a spherical liquid hydrogen storage tank in a microgravity environment occurs at a different rate than in a normal 1-g environment on the ground [577].

A method was developed for computing boil-off losses and the self-pressurization rate along with estimating the growth of the stratified layer for different levels of gravity in a cryogenic hydrogen storage system [578]. The factors that might have an impact on the system include the total heat leak, fill level, axial variation of the heat flux, gravity, and tank size and shape. The model is an extension of the model originally developed by Arnett and Voth. The current model differs from that used by the aforementioned authors in that constant thermophysical properties have been replaced by dynamic properties.

The self-pressurization of large cryogenic storage tanks under microgravity conditions was investigated by coupling a lumped thermodynamic model of the vapor

region with a complete solution of the flow and temperature fields [579]. The results indicated that in microgravity both buoyancy and natural convection are important and play a role in phase distribution and tank self-pressurization. A spherical vapor bubble placed at the center of the tank deforms and moves to one side of the tank before any significant pressure rise. Long-term results obtained with the vapor region near the tank wall showed that, even in microgravity, natural convection leads to thermal stratification in the liquid and alters the pressure rise rate. The final rate of pressure rise agreed with a lumped thermodynamic parameter model of the entire system, but the final pressure levels departed from predicted levels because of initial transients.

Modeling the thermal stratification of cryogenic propellants within the upper stage of a launch vehicle is necessary for mission planning and successful execution. During orbital transfer the upper stage may coast for several hours during which time the propellants are heated by solar radiation. For orbital insertion at the conclusion of the coast the propellants must be within a narrowly defined range of temperature and pressure to ensure engine restart. Several simplified models of thermal stratification were developed which included the low accelerations and thermal conditioning roll ("rotisserie mode") of the upper stage during the transfer coast. These models were used to assess the impact of thermal stratification within generic liquid hydrogen or liquid oxygen tanks over a range of accelerations, spin rates, and incident solar heat fluxes for cylindrical tank geometries [580].

## 5.9 Geysering Problems with Liquid Hydrogen

Geysering is the sudden gushing of a two-phase mixture of liquid and gaseous hydrogen if the liquid that was already near the boiling point but prevented from boiling by the hydrostatic pressure of the liquid column above it suddenly works its way to the surface and starts boiling, similar to geysers observed in geothermal springs. Geysering occurs in vertical pipes or tanks with a high L/D ratio and can occur with any liquid but is troublesome if it occurs unexpectedly with liquid hydrogen or liquid oxygen. Geysering can be prevented by subcooling the cryogenic fluids sufficiently before pumping them through vertical pipes. Vertical pipes are typically encountered at launch sites where the service tower plumbing connects to the umbilical that transfers propellant to the launch vehicle [581, 582].

## 5.10 Sloshing of Liquid Hydrogen

Sloshing of liquids in propellant tanks is a problem with all liquid propellants and not unique with hydrogen. Sudden center of gravity shifts may cause rockets to go unstable. Many propellant tanks have anti-slosh baffles to restrict liquid motion under the effect of lateral forces [583].

Experimental data on the dynamics of liquid hydrogen sloshing in the 6.6-m (260 in.) diameter tank of a SATURN S-IVB stage during boost, at S-IVB stage cut-off, and in orbit indicated that for the boost phase of flight, the amplitude of the sloshing liquid decreased from approximately 0.25 m (10 in.) at the beginning of S-IVB stage boost to a minimum of about 0.038 m (1.5 in.) as the liquid level moved past the baffle [584]. The frequency during the S-IVB stage engine burn increased from approximately .44 cycles per second to .70 cycles per second and showed good agreement with predicted values. During orbital coast phase, periods of the liquid hydrogen oscillation were measured through a range of accelerations from  $8 \times 10^{-5} g_0$  to  $4.4 \times 10^{-4} g_0$ . Period data taken while the acceleration was varying with time did not agree with either the predicted natural or coupled periods. Nearly steady-state conditions existed for the  $8 \times 10^{-5} g_0$  acceleration and the 300–330 s slosh periods measured at this acceleration were close to the predicted value of 315 s. The good agreement between experiment and “high- $g$ ” theory (i.e., a theory neglecting surface tension and contact angle effects) at this very low acceleration tends to verify the validity of the Bond number as a criterion for defining “high- $g$ ” conditions with regard to liquid sloshing.

Similar studies were done for sloshing in a CENTAUR upper stage hydrogen tank [585]. An experiment was conducted to investigate the process of liquid reorientation from one end of a small scale-model CENTAUR liquid-hydrogen tank to the other end by means of low-level accelerations. Prior to reorientation, the liquid was stabilized at the top of the tank at a Bond number of 15. Tanks both with and without ring baffles and with tank radii of 5.5 and 7.0 cm were used in the study. Reorientation acceleration values were varied to obtain Bond numbers of 200 and 450. Liquid fill levels of 20 and 70% were used. From the data in this study, relations were developed to estimate reorientation event times in unbaffled tanks through the point of final liquid clearing from the top of the tank. The insertion of ring baffles drastically changed the reorientation flow profiles but resulted in only minor differences in the times of tank-top uncovering and liquid collection.

Understanding the behavior and response of cryogenic propellants during spacecraft flight operations (e.g., engine restart and fluid transfer) is an extremely important aspect of vehicle design. Accurate predictions of fluid motion and slosh amplification are needed to ensure proper settling prior to engine burn and effective vehicle control throughout all phases of the mission [586].

The technology necessary for acquisition or controlled positioning of liquid and vapor within a tank in reduced gravity to enable single-phase liquid outflow or vapor venting depends on slosh wave excitation induced by the resettling flow field activated by impulsive reverse gravity acceleration during the course of liquid fluid reorientation, disturbed by geysering for liquid filled levels of 30, 50, and 80%, creating slosh waves with various frequencies [587].

Liquid hydrogen that was free-floating in a partially filled tank during the coast phase of an upper stage needs to be settled in a bubble-free condition over the outflow

pipe leading to the pump inlet. Propellant settling is achieved by firing small reaction control thrusters. If the thrust developed by the RCS thrusters is too low, not all propellant may collect at the bottom of the tank. If the RCS thrust is too high and too sudden, the propellant will splash all over and slosh and it will take a long time before it comes to rest. Propellant may enter the outlet duct and geyser back-out, spreading it all over the tank.

### 5.11 Liquid Hydrogen Propellant Management in Zero-*g* and Reduced Gravity

As with all liquid propellants, it is a problem to separate the liquid phase and the gas phase of liquid hydrogen and gaseous hydrogen in a zero-*g* environment to avoid bubble ingestion into liquid going through the pumps and loss of liquid when the ullage gas space needs to be vented. Boil-off during the coast phase has to be vented such that only gas is vented and no liquid is wasted. In most cases where upper stages using liquid hydrogen have to be started more than once, a propellant settling burn performed by a storable propellant auxiliary propulsion RCS system precedes the main engine re-ignition. For longer coast phases, the upper stage may be spun up to achieve phase separation with a bubble along the axis of the rotating tank and direct the propellant toward the galleys along the walls.

Positive expulsion propellant management devices like flexible bladders and diaphragms that can be used with storable propellants are out of the question for cryogenic propellants because all materials become too brittle at the liquid hydrogen temperature [588]. In spite of the embrittlement, bladders made from multiple layers of Mylar, Kapton, and a polyester film were tested for the expulsion of liquid hydrogen, and several filling/expulsion cycles were completed before the bladders started leaking [589].

Alternative methods for propellant management of liquid hydrogen in zero-*g* have been evaluated but have not yet flown. Passive propellant management devices depend on surface tension. Surface tension propellant management devices have been tested for liquid hydrogen. The surface tension and the wetting angle is sufficient that tank walls and wire mesh structures are completely wetted by liquid hydrogen in zero *g* [188, 190, 191].

It has also been attempted to collect non-conductive cryogenic liquids like LH2 in a zero-*g* environment by electrostatic fields and dielectric forces between the two plates of a capacitor [590, 591]. These propellant containment methods are also called “electrohydrodynamic propellant containment systems” or “dielectrophoretic propellant orientation systems.” This method would also work for other, non-conductive liquids other than liquid hydrogen. A converging plate system was designed to operate at 100 kV [592, 593]. For a tank containing 5400 kg (1200 lb<sub>m</sub>) of LH2, the power consumption would be 10 W. This method has been tested with LH2 and it was noted that evaporative losses were reduced by 20% because the liquid was levitated between the

capacitor plates at the location of the highest field strength and less of it was in direct contact with the walls. Concern is that electrical discharges could upset this propellant management scheme. The voltage applied to the capacitor plates must remain below the breakthrough voltage of hydrogen. It is not clear if the electrostatic forces are strong enough to keep the propellant in position once it starts boiling again.

The fourth and eighth ATLAS-CENTAUR upper stages (AC-4 and AC-8) were launched to study cryogenic propellant management during orbital coast phases in zero- $g$  [594]. The AC-4 flight showed that propellant management cannot be defined solely by the Bond number (ratio of acceleration to surface tension forces). On the AC-4 flight, kinetic energies imparted to the liquid hydrogen at first engine cut-off caused excessive liquid motion within the hydrogen tank, resulting in subsequent venting of liquid hydrogen rather than gaseous hydrogen. The vented liquid impinged on the vehicle causing it eventually to tumble out of control. The AC-8 vehicle was modified to reduce and/or control the energies transmitted to the propellant at cut-off. Energy dissipators were installed on the hydrogen tank pressurization line and boost pump return flow lines. A balanced thrust hydrogen vent system was installed to reduce vehicle disturbances. A slosh baffle was installed in the hydrogen tank.

A CFD model was used to study the effect of reduced gravity on the thermal performance in a liquid hydrogen tank [595]. Four gravity levels ( $1g$ ,  $10^{-1}g$ ,  $10^{-2}g$ , and  $10^{-3}g$ ) were compared to identify the influence of the reduced gravity on fluid thermal stratification. The results showed that with the increasing gravity level, the vapor temperature distribution becomes more uniform, and the liquid stratum layer develops faster. Comparing the CFD results with the results of two stratification theoretical models, the stratum thickness calculated by CFD model was close to the values of other models. Under the influence of surface tension in reduced gravity, liquid close to the tank wall moves up with the interface becoming curved. The interface area rises with the decrease of gravity.

A computational model for the liquid-vapor phase change was developed to investigate the thermal physical process in a liquid hydrogen (LH2) tank in reduced gravity [596]. Viscous flow was considered in the model with natural convection. The stratified layer parameters, the tank pressure rise rate, and the interface phase change were studied, and the influence of the initial liquid height, the initial ullage temperature and the tank wall heat flux on the development of thermal stratification was estimated. The results showed that the stratified layer thickness increased with the initial liquid height. While the initial liquid height is large, it takes more time for the complete development of fluid thermal stratification. Largely influenced by the temperature of the stratified layer, both tank pressure and phase change capacity increase with the initial liquid height. It seems that the initial ullage temperature has a weak effect on the development of fluid thermal stratification. Both the tank pressure and the phase change quality increase with the initial ullage temperature. The external tank wall heat flux promotes the development of thermal stratification. The stratified layer

has a larger thickness and develops faster for the larger heat flux. Both tank pressure and phase change capacity increase with the external heat flux.

A study on fluid flow and heat transfer of liquid hydrogen in a zero boil-off cryogenic storage tank in a microgravity environment used a storage tank that was equipped with an active cooling system consisting of a heat pipe and a pump-nozzle unit [597, 598]. The pump collected the cryogen liquid and discharged it through a nozzle onto the evaporator section of the heat pipe in order to prevent the cryogen from suffering boil-off losses due to the heat leaking through the tank wall from the surroundings. A three-dimensional finite element model was used in a set of numerical simulations to solve the velocity and temperature fields of liquid hydrogen under steady-state conditions. Parametric study results from both models predicted that as the speed of the cryogenic fluid discharged from the nozzle increased, the mean or bulk cryogenic fluid speed increased linearly, but the maximum temperature within the cryogenic fluid decreased.

#### **5.11.1 Venting of Hydrogen Boil-off in Zero-g**

Vapor venting to relieve tank pressure can be accomplished easily on the Earth's surface or during powered flight because the liquid and vapor occupy predictable positions within the tank and a simple vent pipe can be employed; however, under low-gravity conditions the vapor/liquid distribution in the tank can shift unpredictably as the result of small disturbing forces. Prior to re-igniting the main engine(s), small RCS thrusters are usually fired to re-orient the liquid and vapor and settle the liquid in one end of the tank, but the thruster firing affects vehicle orbital parameters. The thrusters consume propellant for any but very low acceleration levels and long settling times. It is important, therefore, to develop more efficient methods for venting vapor [599]. While a propellant settling maneuver, typically done for only one or a few restarts, would solve the ullage gas venting problem at the same time, it requires more propellant from the small RCS thrusters than when gas venting only is desired. Gas venting for longer coast phase missions can be achieved without settling all the propellant near the drain hole and with less propellant consumed by the RCS thrusters. Several methods to achieve venting without liquid propellant loss have been evaluated [600]. In a CENTAUR upper stage, a center vent tube was supposed to allow gas venting with a minimum of RCS thruster firing [601].

It was found to be feasible to vent a partially filled liquid hydrogen tank in an orbiting SATURN S-IVB stage in space continuously or intermittently by applying a small acceleration to keep the liquid hydrogen settled at one end of the tank [602]. Results of venting liquid hydrogen tanks in reduced gravity can be compared to venting tests performed under normal gravity [603].

Zero-gravity venting and surface tension screen baffle integration for orbital storage and transfer of liquid hydrogen were examined by analytical and experimental methods [604]. A full wall-screen liner was supposed to keep the liquid puddled in

the desired location. The screen bubble point, flow-through pressure loss and pressure loss along rectangular channels lined with screen on one side were measured for LH<sub>2</sub> saturated at 344 kPa (50 psia).

Instead of venting and losing the hydrogen boil-off while in orbit around the Earth, a solar-thermal rocket was proposed that would maintain the tank at a temperature such that all hydrogen withdrawn from the tank is used for active propulsion, in this case a solar-heated heat exchanger in the focal point of a collector mirror to provide rocket propulsion during a 30-day mission for LEO-GEO transfer [605].

### 5.11.2 Venting of Liquid Hydrogen Boil-off in a Vacuum

Assuming that the boiling liquid and the evolved gas can be separated, the boil-off during a coasting phase must be vented to outer space without causing uncontrolled thrusting (must use a pair of thrust-neutralizing nozzles) or disturbing the required orientation of the spacecraft with regard to the Sun or Earth. When the pressure of a liquid drops below its triple point, a phase transformation occurs forming both solid and gas phases with no remaining liquid. Liquid cryogenics vented from launch vehicles, such as the CENTAUR upper stage, will undergo such a transformation when exposed to pressures below their triple points. Solids thus formed may accumulate in the overboard vent, restricting flow and possibly blocking the vent.

When venting boil-off from cryogenic propellants in outer space, one must be aware that expanding gases near their boiling point can cool adiabatically to the point where they condense and freeze. Solid hydrogen might clog the lines or the valves through which it is expanded into vacuum [606, 607].

A test program was conducted to determine if solid hydrogen would form, adhere to the walls, and block the RL-10 engine vent ducts during a CENTAUR upper stage retro maneuver [608]. Results showed that solid hydrogen forms in the ducts and adheres to the interior surfaces of the vent tube, intermittently building up and breaking off into the gas stream. Approx. 80% of the vent tube exit area was choked by frozen hydrogen.

If liquid hydrogen stored at 1 atm is flashed into vacuum and allowed to go to triple point conditions, about 80% of it will solidify in the form of solid hydrogen “snow” [609]. In a similar situation with LOX, about 70% of it will solidify to oxygen “snow.”

An investigation of vent blockage was performed using saturated liquid argon as a substitute for LOX or LH<sub>2</sub> [610]. Observations of solid adherence and accumulation were recorded for various argon delivery pressures. Wall adherence and vent blockage was strongly dependent on delivery pressure, with accumulation increasing for decreasing pressure. For low delivery pressures, relative to the triple point, vent blockage was immediate and complete. In addition, solid formation was observed to propagate into the liquid, against the direction of flow, revealing the porous nature of the solid as well as the impact on the flow.

## 5.12 Chillover of Cryogenic Equipment

The calculation of evaporative losses during chillover of cryogenic equipment would apply to liquid oxygen systems just as well as liquid hydrogen systems. It is just that with liquid oxygen systems it is easier to vent the gases than with vented hydrogen or liquid methane that has to be ducted to a vent stack and flared off. One can minimize or avoid altogether evaporative losses by using chilled helium to precool the receiving equipment before dropping liquid propellant into it, but this is a very expensive option.

Measurements on the chillover and steady-state boil-off losses of a 189-m<sup>3</sup> (50000 gallon) evacuated perlite insulated liquid-hydrogen storage Dewar at the Nuclear Rocket Development Station in Nevada showed that this tank required less liquid hydrogen for chillover and the steady-state heat flux was less than by a factor of 2 from what conservative calculations had predicted [611, 612].

Results of these observations are directly applicable to large Dewar storage vessels currently being designed, built, or being placed into service. These results should assist the designer and planner in estimating the cryogen quantities required for chillover and may even in some cases aid in evaluating the relative merits of different types of insulation systems available.

A computer model was used to perform an analysis of non-vented fill techniques on a 4.96 m<sup>3</sup> light weight liquid hydrogen tank (which was similar in size and shape to the tankage planned for a COLD-SAT liquid hydrogen flight experiment), and was used to select one of two injection systems for non-vented fills of this tank at design flow rates between 220 and 450 kg/h [613]. The first system used multiple nozzles spraying from the top of the tank through the ullage space. This system should be capable of liquid fill levels in excess of 95%. The second system injected the liquid through a submerged nozzle and should produce fill levels on the order of 80% liquid.

A series of no-vent fill experiments were conducted on a 4.96-m<sup>3</sup> (175-cu. ft.) flight weight hydrogen tank using two different inlet systems (top spray and bottom spray) at different tank initial conditions and inflow rates [614]. Nine tests were completed of which six filled the tank to better than 94%. The experiments demonstrated a consistent and repeatable ability to fill the tank in excess of 94% using the non-vented fill technique.

Liquid hydrogen no-vent fill tests were performed using various size spray nozzles and a spray bar with different hole sizes in a 142-L (5-cu. ft.) receiver tank [615]. Fill levels of 90% by volume or greater were achieved while maintaining a receiver tank pressure below 207 kPa (30 psia). Spray nozzles were mounted at the top of the tank, whereas the spray bar was centered in the tank axially. Both liquid injection techniques tested were capable of filling the receiver tank to 90% under variable test conditions. The spray nozzle injection technique was more effective in minimizing the receiving tank pressure throughout a no-vent fill compared to the spray bar under normal gravity conditions.

For best results in a cryogenic pipeline and minimum propellant lost during chill-down, high vacuum is used as the insulation in the annulus between two concentric tubes with the cold fluid flowing through the center tube [616].

A facility was designed for cold-flow development testing of the M-1 LOX/LH2 rocket engine fuel and oxidizer turbopump assemblies based on thermal and stress analysis of initial chilldown of large diameter cryogenic piping systems [617]. Various methods were considered for chilldown of cryogenic piping systems. Consideration was given to LH2 and LOX propellant systems that utilize the cryogenic boil-off gases at a predetermined rate to achieve system chilldown. The use of this technique reduces or eliminates the problem of thermal stress concentrations in the system materials during chilldown. The transient chilldown of a single thick-walled tube by liquid and gaseous hydrogen was measured and parameterized for future designs of larger pipes carrying liquid hydrogen [618].

It would be very costly to keep a cryogenic pipeline cold all the time between uses. Cryogenic pipelines see a lot of transient operating conditions during pre-use chilldown and post-use thawing. An uncooled pipeline which is used to transfer a cryogenic fluid from one point to another must go through a period of cooling down from ambient temperature to near the liquid boiling temperature. During most of the cooldown period the liquid boils and the pipeline delivers only warm gas. The time required to achieve bubble-free flow can be estimated from a dimensionless parameter read from a graph based on knowledge of the fluid and pipe enthalpy, density, and velocity of sound in the warm gas [619]. The predictions from this method were compared to experimental results.

Two finite difference computer models, aiming to predict no-vent fill either in normal gravity and or in microgravity environments, were developed to investigate the filling performance in a liquid hydrogen tank [620]. In the normal gravity case model, the tank/fluid system was divided into five control volumes including ullage, bulk liquid, gas-liquid interface, ullage-adjacent wall, and liquid-adjacent wall. In the microgravity case model, the vapor-liquid thermal equilibrium state is maintained throughout the process, and only two nodes representing fluid and wall regions were applied. To predict the liquid-wall heat transfer accurately, a series of heat transfer mechanisms were considered and modeled successively, including film boiling, transition boiling, nucleate boiling and liquid natural convection. The two models were validated by comparing their predictions with experimental data, which showed good agreement. Then the two models were used to investigate the performance of no-vent fill under different conditions. It was showed that in the normal gravity environment the no-vent fill experiences a continuous pressure rise during the whole process and the maximum pressure occurs at the end of the operation, while the maximum pressure of the microgravity case occurs at the beginning stage of the process. Reducing inlet liquid temperature by subcooling can improve the filling performance in normal gravity but cannot significantly reduce the maximum pressure in microgravity.

### 5.13 Reliquefier and Condensers on Hydrogen Storage Tanks

If weight and power requirements permit, boil-off from hydrogen tanks can be condensed and returned to the tank. Such systems are called “reliquefiers.” They depend on a source of cold provided by cryocoolers. This would enable zero boil-off storage and would extend or even enable some missions. This would not only reduce or prevent boil-off vaporization losses, but it would also subcool and densify the propellants. Densified and slush propellants are discussed in section “Subcooled and Slush Hydrogen.” The reliquefaction and cooling systems described here for liquid hydrogen would work for extending the storage time of liquid oxygen on long-term missions as well.

Reliquefaction would be very useful in combination with propellant scavenging of unused propellants from upper stages before they are sent into a destructive re-entry and burn up in the atmosphere. At one time it was considered to bring the Space Shuttle external tank with the orbiter all the way up into orbit and transfer the unused propellant to a propellant depot. The orbital propellant depot would have needed a reliquefaction and cryocooling system to maintain its stockpile of liquid hydrogen and liquid oxygen.

Reliquefaction of all or part of the boil-off hydrogen vapor is being considered as a means of reducing or eliminating boil-off losses from propellant tanks during long-term missions in Earth orbit [621]. Both closed and open cycle reliquefier systems can offer weight savings and make certain missions possible that previously were not. Furthermore, the reliquefier can be optimized in conjunction with superinsulation for optimum results. For short missions, insulation would be more economical. For very long-duration missions, reliquefaction becomes more economical. The optimum insulation mass will be less for a system with a reliquefier than for a system without a reliquefier providing that certain conditions are met.

Partial hydrogen reliquefiers, having certain estimated mass and power requirements, can produce significant payload improvements in space missions requiring long-term storage of liquid hydrogen [622].

Five different cooling methods were evaluated for closed cycle reliquefaction long-term cryogenic storage: Stirling cycle, Vuilleumier refrigerator, separable component systems, Brayton refrigerator, Claude refrigerator, and Joule-Thomson refrigerator [623–625].

Cryocooler and passive insulation technology advances have substantially improved prospects for zero-boil-off cryogenic storage [626]. A large-scale, zero-boil-off demonstration at the NASA MSFC Multipurpose Hydrogen Test Bed used a commercial cryocooler with an existing spray bar mixer and insulation system in a manner that enabled a balance between incoming and extracted thermal energy.

Long duration space missions with liquid hydrogen depend on reducing boil-off losses. One way to control tank pressure and minimize boil-off losses involves the use of a subcooled axial liquid jet to both thermally destratify the bulk liquid and remove

energy from the tank. This method is called “jet mixing” [627]. The effectiveness of using subcooled jet mixing as a pressure control scheme was analyzed by performing a small-scale experiment in a normal gravity environment with a refrigerant [628]. Following a period of self-pressurization, the jet’s speed and degree of subcooling were parametrically varied so that relevant trends could be identified. Experimental results showed that mixing the bulk liquid is not sufficient to control pressure. To sustain any pressure reduction, substantial subcooling of the mixing jet is necessary. The rate of pressure and vaporization losses reduction is greater for increased jet speeds and subcooling. Analytical and computational models were developed in order to predict the self-pressurization behavior. Model comparisons revealed that generally a thermodynamic model underpredicts the self-pressurization and depressurization rates. The lack of agreement was primarily attributed to the homogeneity assumption inherent in the model. To improve model predictions, a zonal model was developed which avoids the global homogeneity assumption. Comparisons between the experimental data and the zonal model predictions were excellent for moderate to high jet flow rates. For slower jet speeds, buoyant flow in the bulk liquid adversely affected the effectiveness of a subcooled mixing jet and a more detailed computational model would be required to capture this intraphase phenomenon.

In order to avoid venting during liquid hydrogen storage and in order to decrease propellant vaporization loss in space application, a numerical study was performed of the thermal performance of a hydrogen storage tank with nozzle injection and a new improvement, a guide tube [629]. Compared with the previous storage tank design without a guide tube, the chilling performance of the new storage system was enhanced since the guide tube improved the heat transfer and reduced the stagnant region to meliorate the flow circulation. Distribution profiles of temperature and velocity in the storage tank have been attained to evaluate the chilling and mixing performance. The key geometric parameters were further optimized by analyzing a series of cases under different geometry settings, from which the optimized ranges of dimensionless parameters have been obtained and studied.

A series of tests was performed to demonstrate the capability of using integrated refrigeration and storage to remove energy from a liquid hydrogen (LH2) tank and control the state of the propellant [630]. A primary test objective was the keeping and storing of the liquid in a zero boil-off state, so that the total heat leak entering the tank is removed by a cryogenic refrigerator with an internal heat exchanger. The LH2 is therefore stored and kept with zero losses for an indefinite period of time. The LH2 tank in this case was a horizontal cylindrical geometry with a vacuum-jacketed, multi-layer insulation system and a capacity of 125000 liters. The closed-loop helium refrigeration system was a Linde LR1620 capable of 390 W cooling at 20K (without any liquid nitrogen precooling). Three different control methods were used to obtain zero boil-off: temperature control of the helium refrigerant, refrigerator control using the tank pressure sensor, and duty cycling (on/off) of the refrigerator as needed.

Cryocooler technology is needed at 20 K to achieve zero boil-off of liquid hydrogen and at 90 K to achieve zero boil-off of liquid oxygen or liquid methane as well as to liquefy oxygen or methane that is produced by *in situ* resource utilization on the surface of Mars [631]. Progress has been achieved with reverse turbo-Brayton cycle cryocoolers, where the specific power and specific mass have dropped, decreasing the mass and power requirements of these cryocoolers.

Thermoelectric refrigeration and thermomagnetic refrigeration were considered as a means to preserve solid hydrogen on board of interplanetary space vehicles so it could be used for the return trip back to Earth [632].

#### 5.14 Supercritical Storage of Hydrogen

Boiling point and critical point of hydrogen are very close together, unlike the properties of any other gas used as a rocket propellant. The boiling point is at 20.27 K, and the critical temperature is at 33.3 K. In addition, the critical pressure is so low (1.297 MPa = 12.8 atm) that it is easily exceeded with moderate storage tank pressures.

Supercritical storage of hydrogen (and oxygen) has been used to supply hydrogen (and oxygen) to fuel cells operating in zero-*g* environments during the GEMINI, APOLLO, and Space Shuttle missions. The advantage of supercritical storage is that the tank contains neither liquid nor gaseous phases and that one no longer has to worry about the physical state if propellant is drawn from the tank in a zero-*g* environment. Several companies, including Beech Aircraft Corp., developed supercritical storage tanks for hydrogen [244].

Conceptual space transportation vehicles and their orbital facilities, which may use single-phase, supercritical cryogenic propellants, have been compared with conventional subcritical, two-phase orbital propellant storage concepts. The study was motivated by the desire to avoid fluid-management problems associated with the storage, acquisition and transfer of subcritical liquid oxygen and hydrogen propellants in the low-gravity environment of space. Although feasible, the supercritical concepts suffer from weight and propellant resupply system power requirements that make the concepts impractical [633, 634].

#### 5.15 Cavitation of Liquid Hydrogen

Cavitation of liquid hydrogen in the inlet section and on the propeller tips of hydrogen pumps is a serious design problem and various techniques to prevent cavitation have been discussed here. Cavitation is defined as the formation, caused by a reduction in pressure, of a vapor phase within a flowing liquid or at the interface between a liquid and a solid. Since the formation and collapse of vapor cavities alters flow patterns, cavitation may reduce the efficiency of pumping machinery, and reduce the precision of

flow measuring devices. Collapse of these vapor cavities can also cause serious erosion damage to fluid-handling equipment. Cavitation can occur in any flow passage. The best way to study and visualize cavitation is in transparent cavitating venturi [635]. Conventional cavitation-inception parameters and head-velocity curves in liquid hydrogen were derived over a range of experimental temperatures (20.3–22.8 K = 36.5–41°R) and inlet velocities (21–56 m/s = 70–185 ft/s). Minimum local wall pressure at incipience was calculated to be less than bulk stream vapor pressure by as much as 100 m (328 ft) of hydrogen head in some inception tests.

## 5.16 Subcooled and Slush Hydrogen

Evaporative losses during transfer of liquid hydrogen can be minimized if the liquid is cooled to below the boiling point or even to near the freezing point. The designation “supercooled” hydrogen is not correct, because it would apply only to a liquid that has been supercooled to below its natural freezing point, but it failed to crystallize and instead supercooled and remained in a metastable state due to a lack of condensation nuclei. We prefer to call the condition of cold hydrogen at temperatures between its natural boiling point and its freezing point “undercooled” or “subcooled” instead of “supercooled” hydrogen. Undercooled, single phase liquid hydrogen is not in a metastable state and is in equilibrium with its surroundings. Undercooled, two-phase hydrogen is called “slush hydrogen” and it will be discussed later in this section. The density increase for densified hydrogen is 8%, and the density increase for slush hydrogen is 15%.

Supercooled hydrogen may exist when hydrogen is cooled to temperatures below the freezing point in a very clean, particle-free environment free of condensation nuclei. It has been speculated that it may be possible to supercool liquid H<sub>2</sub> and keep it as a liquid below its normal freezing temperature [636]. It was theorized that there is a significant prospect that H<sub>2</sub> could be supercooled to arbitrarily low temperatures, and that in this way superfluid H<sub>2</sub> might be produced.

### 5.16.1 Subcooled Homogeneous Liquid Hydrogen

In the early years of hydrogen cryogenics, the application of subcooled hydrogen was mostly directed towards specific vehicle systems. The use of hydrogen in its subcooled state, however, should be considered for any system anticipating the need for hydrogen. A trade-off must be made between whether one should be using subcooled or slush hydrogen for a specific mission. One must decide whether the primary effort should be directed toward the application of liquid hydrogen, subcooled liquid hydrogen or slush hydrogen [637, 638]. Ground handling of subcooled hydrogen is not much different from that of liquid hydrogen. Undercooled (subcooled) liquid oxygen [639] is

already used routinely by SpaceX on its Falcon launch vehicles, so the next step would be to use this technology with liquid hydrogen as well.

In the cryogenic engineering literature it is sometimes not quite clear if the term “densification” includes a phase change to frozen hydrogen or if it only means to cool the liquid hydrogen to near its triple point. Unless the term “solid hydrogen” or “slush hydrogen” is used in the title or abstract, we assume that densification papers deal only with subcooled hydrogen.

The X-33 project, NASA’s short-lived technology demonstrator for the next Reusable Launch Vehicle (RLV), revived interest in densified cryogenic propellants [640–642]. Densified hydrogen was also planned to be used for its sequel, the full-scale Venturestar, a SSTO RLV [643]. The heat exchanger for subcooling the hydrogen was developed based on an analytical model [644, 645].

A test program was conducted to demonstrate the ability to load densified (DLH2) into a subscale propellant tank [646]. The multi-lobe tank, which was made from composite materials similar to that to be used on X-33, was formed from two lobes with a center septum. Test results were compared to analytical predictions. Data collected for this test series agree well with analytical predictions of the environmental heat leak into the tank and the thermal stratification characteristics of the hydrogen propellant in the tank as it was filled with DLH2. The results from the recirculation tests with liquid oxygen have confirmed the mathematical model [647].

Densification of both LOX and LH2 was considered for the STS Space Shuttle, but was never implemented [648, 649]. It remains to be seen if it can be used for the Space Launch System.

Subcooling LOX has now become a routine operation for the Falcon-9 launch vehicle, allowing more propellant to be loaded into a given tank volume and reducing the flow rate at which the tank has to be topped off from an umbilical cryogenic line during countdown until immediately prior to launch. Using a similar subcooling technology for hydrogen is the next step.

### 5.16.2 Slush Hydrogen

The technology for undercooling liquid hydrogen and making slush hydrogen was developed in the late 1960s and various types of equipment were offered for this purpose (Table 46).

#### 5.16.2.1 Production of Slush Hydrogen

The slush hydrogen production methods include evaporative cooling processes, such as the freeze-thaw process [670] and the spray technique [671] and refrigeration processes, such as auger [672] and magnetic refrigeration [673, 674].

There are several recognized methods of producing slush hydrogen [675]. One is the auger method. An auger rotating inside a brass tube refrigerated with liquid helium

**Table 46:** Literature summary for slush hydrogen technology.

was used to produce liquid-solid (slush) mixtures of hydrogen and of oxygen [672, 676]. The auger produced small particles from the cryogenics so that the resulting slush mixture could be transferred and stored. The auger could produce slush continuously in an appropriate system; it could produce slush at pressures higher than the triple point pressure of the cryogen, and the energy required to produce the slush was less than the energy required to produce slush using the freeze-thaw process.

The auger method simply uses an auger rotating inside an externally insulated refrigerated cylinder that is submerged in liquid hydrogen. Hydrogen freezes on the internal walls of the cylinder and is continuously shaved or scraped off by the auger. The auger method with a 178-mm (7-in.) diameter auger type hydrogen slush generator can be used in a continuous production mode and produces slush hydrogen at superatmospheric pressures so that the slush can be pressure-transferred to storage containers [677].

Similar auger methods are described in [678]. It was observed that the particle size of slush hydrogen produced by the auger method was smaller than that obtained with a freeze-thaw process. A propeller was installed at the bottom of the inner vessel to mix solid with liquid thoroughly and keep the solid in suspension [679].

Another method for making slush hydrogen is the freeze-thaw method. The freeze-thaw method has been used to generate small and relatively large quantities of slush hydrogen [680]. This production technique requires that the ullage over a fixed volume of liquid is vacuum pumped until a solid layer forms at the liquid-vapor interface. The vacuum pumping is then stopped and the solid layer melts (thaws) and settles into the liquid. This cycle is repeated until the desired solid content has been formed. The solid is then mixed with the liquid by stirring to form a homogeneous mixture of solid and liquid. The porosity of the solid formed in this manner is a function of the pumping rate. Slow pumping rates produce a dense solid which when broken forms large particles of solid and will not form a homogeneous mixture with the liquid. Higher pumping rates produce a porous solid which is easily broken into much smaller particles and is easily mixed with the liquid to form a homogeneous mixture, which may be defined as slush. Disadvantages of the method are: **(1)** not all cryogenic tanks are designed to operate at negative pressure. A safety hazard exists because the required triple point low ullage pressures (0.0061 MPa) invite air leakage into the slush container and oxygen/hydrogen mixtures are an explosive hazard, and **(2)** transfer of slush into a storage container requires ullage pressurization or pump-transfer. **(3)** This is a batch process and not easily scaled up to continuous operation. Maximum solid fractions achieved to date are 60%, with 40 to 50% solid content being practical and easily accomplished.

Subcooled liquid hydrogen can be produced by several different methods:

- a. By pumping off the gas space above liquid hydrogen, additional liquid hydrogen must evaporate and the heat of evaporation is extracted from the liquid, which can theoretically cool all the way down to the triple point [609].
- b. By passing cold helium through an external cooling jacket or a cooling coil that is immersed in the liquid hydrogen tank.
- c. Liquid hydrogen can be compressed isothermally and expanded isentropically.
- d. By passing cold helium gas directly through the liquid hydrogen (if the dilution of  $\text{LH}_2$  by dissolved He can be tolerated).

The concept of subcooled hydrogen was demonstrated by using method **(a)** in a laboratory test [681]. About 9 kg liquid hydrogen can be cooled from 20.4 to 13.9 K by sucking off 1 kg hydrogen as vapor at low pressure. If one wants to prepare slush hydrogen, an additional 130 g of hydrogen must be vaporized for each kg of solid hydrogen desired. If one wants to make 100 kg hydrogen slush with a solids content of 50%, one must start with 117 kg of liquid hydrogen. The hydrogen gas that is pumped off does not have to be discarded but can be fed to a liquefaction plant and recycled.

It would be most energy efficient and avoid an additional heat exchanger to pump cold gas, but it is difficult to operate a vacuum pump at 13–25 K. A cold pump would be more compact than a warm pump. If the gas is allowed to warm before it is pumped, the pump has to be bigger and has to perform more work because a larger volume of gas needs to be moved. If hydrogen slush is made by passing liquid helium through

a cooling jacket or an internal cooling coil (method **b**) and allowing the helium to evaporate, one will need 1 kg of liquid helium for each kg of solid hydrogen. The hydrogen would have to be well stirred to prevent the build-up of solid hydrogen crusts on the cooling coils. A crust of solid hydrogen would impede all further heat exchange. The concept of cyclic compression-expansion (method **c**) is theoretically promising, but has not yet been demonstrated.

The direct injection of cold helium gas into liquid hydrogen was tested in a laboratory experiment [682]. One has to remember that some of the helium will dissolve in the hydrogen. The direct injection method has been used for subcooling LOX [639].

Liquid-solid mixtures of hydrogen (slush hydrogen) were produced by vacuum pumping, gaseous He injection with vacuum pumping, and by cooling with liquid He in a low-heat-leak apparatus that permitted visual observation of the experiments through a periscopic device [683].

At one time, the large-scale slush hydrogen facility at Wright Patterson Air Force Base was the largest of its kind in the US [684]. The purpose of the facility was to simulate operational scale equipment while maintaining the flexibility of small-scale research apparatus.

A slush preparation method by intermittent vacuum pumping was developed [685]. Slush was aged 100 h during which time solid particle size and structure were observed for eventual particle growth by agglomeration. The solid particle structure changed dramatically during aging, even though the particle size changed insignificantly. The solid particles were observed to change from particles with irregular rough edges to particles with smooth edges. The smaller particles would tend to combine with the larger particles to form a particle of higher density. Slush with over 50% solid content can be transferred and pumped with losses similar to losses in triple-point liquid hydrogen if Reynolds numbers are high. Transfer losses in a smooth pipe were 10% less with slush of 30% solid content than with triple-point liquid when the Reynolds number was  $7 \times 10^5$  or greater. Although some special techniques are required for handling slush hydrogen, after some practice it has the characteristics of a simple cryogenic fluid for most applications.

The spray-freeze method creates hydrogen slush with very small particle sizes that can be pumped with a minimum of pressure loss. This produces a better slush product than the freeze-thaw technique, which continuously injects liquid hydrogen at or near its triple-point temperature into a slush hydrogen generator, forming solid hydrogen by removing hydrogen vapor from the slush hydrogen generator [686]. By alternately adjusting the pressure in the slush hydrogen generator to a pressure below the triple-point of hydrogen and then to a pressure slightly above the pressure at the triple-point causes the formation and dispersion of solids on the surface of the liquid hydrogen. To obtain finely grained hydrogen slush suitable for use in a rocket engine, it is necessary to destroy the crystalline surface solid by stirring, but this gives a very coarse

particle size slush. A finely grained slush can be obtained by expanding high pressure liquefied gas through a spray nozzle into a chamber ultimately to a pressure below the pressure of the triple-point in the gas-solid range and then to a pressure above the pressure of the triple point in the gas-liquid range. A high production rate, continuous production, slush hydrogen generator included a tank, a vacuum pump, and delivery of triple-point liquid hydrogen spray to the tank [687].

A handbook of physical and thermal property data for hydrogen in the region between the triple point and the critical point is available and is needed for study of hydrogen slush utilization [76]. The properties are given in both English engineering and SI units. The application of triple-point and slush hydrogen to three space missions was studied. These three space vehicles were the SATURN V S-IVB, a Lunar Mission Landing Vehicle, and a 120-day Earth Orbital Hydrogen Tanker. The SATURN V S-IVB application was based on performance of an advanced lunar logistics mission. In this concept, the S-IVB would be modified from the existing SATURN V APOLLO booster stage to a lunar cargo-landing vehicle. This would require a much longer duration for in-space storage of hydrogen slush turning to liquid [688].

A mission study looked at the use of subcooled liquid and hydrogen slush in a SATURN SIVB stage for a manned Mars fly-by mission [689]. It was concluded in the initial hydrogen slush study program that experimental work was needed on a scale larger than that conducted by the Cryogenic Engineering Laboratory of the National Bureau of Standards at Boulder, Colorado, to determine the practical aspects of applying slush hydrogen to existing or new space vehicles. To perform this experimental work, Lockheed provided a Cryogenic Vehicle Flight Simulator, a slush hydrogen manufacturing Dewar, a slush hydrogen storage Dewar, a 41.5-in. insulated flight-type propellant tank, and the necessary plumbing and controls located at the Lockheed Santa Cruz Test Base to provide realistic tools to conduct an experimental program [690].

Slush hydrogen offers certain advantages for transportation and storage on Earth as well as in space. In the last century, liquid hydrogen was transported between Florida and California in 107000-L tank cars filled to 95% of the tank volume. The trip took 9 days and the evaporation losses were 5.2%. If the hydrogen had been cooled to the point where it consisted of 75% solid and 25% liquid hydrogen, not only would there not have been any evaporation losses during transport, but the tank could also have been kept idle for another 62 days before the tank pressure exceeded the pressure rating the pressure relief valve started venting. Another advantage is that the density of the subcooled hydrogen is higher, such that the same tank volume can hold 16% more propellant. But one must allow for space if the propellant warms up and expands again.

That would be a significant advantage for upper stages where propellant tanks have to be fitted into a limited envelope. That advantage applies only for the trans-

port of hydrogen into orbit where it is stored at an orbital refueling station. There is currently no way to feed slush hydrogen into a rocket engine.

Slush hydrogen may offer certain advantages, but some practical problems have not yet been solved. If hydrogen slush must be transferred from one storage tank to another tank, or from a flight tank into a combustion chamber, one must first develop a pump capable of pumping hydrogen with a certain solids content. It was assumed that current design centrifugal pumps will be capable of pumping LH<sub>2</sub> with up to 20% solids content without too much difficulty. If one uses pressure-fed instead of pump-fed transfer, it might be possible to transfer hydrogen slush with up to 60% solids as long as the hydrogen crystals are finely dispersed and do not cake together.

Before hydrogen slush technology can advance to the next stage, one must develop fast analysis methods that allow the operator to monitor the progress of solidification and verify the solids content of a propellant even after it has been sitting around for several days. One way to predict the amount of solid hydrogen in the slush is to measure the mass fraction of gas pumped off and the rate of heat leaking into the container [691, 692].

Ground service equipment and flight vehicle system requirements were evaluated for the use of densified cryogenic propellants in advanced space transportation systems [693]. Propellants studied were slush and triple-point liquid hydrogen, triple-point liquid oxygen, and slush and triple-point liquid methane. Areas of study included propellant production, storage, transfer, vehicle loading, and system requirements. A saving of approximately  $8.2 \times 100000$  kg was predicted in single stage to orbit gross liftoff mass for a payload of 29484 kg by utilizing densified cryogenics in place of normal boiling point propellants.

A 178-mm diameter auger-type hydrogen slush generator with a supercritical helium flow loop, which simulates the performance of a helium refrigerator and cools the generator was modeled [677]. The coolant temperature was assumed to vary down to 5 K and the flow was assumed to vary about the 1.4 L/s (3 cfm) design point. The computer model of the auger-type generator showed that coolant temperature and auger speed have the greatest influence on slush production rate, although coolant flow rate and auger radial clearance are also important. Three slush hydrogen production methods were tested in the laboratory and compared: the spray method, the freeze-thaw method, and the auger method [694].

An excellent summary of the thermophysical properties, freeze-thaw and auger methods for production, measurement techniques for density and mass flow meters, pressure drop reduction and heat transfer deterioration in pipe flow, and nucleate pool boiling heat transfer properties associated with slush and liquid hydrogen is given in [695].

A demonstration of advanced liquid hydrogen storage techniques included the production of large quantities of densified liquid and slush hydrogen in a 125000-L

tank [696]. Densified hydrogen was produced at three different liquid levels and LH2 temperatures were measured by 20 silicon diode temperature sensors. Overall densification performance of the system was explored, and solid mass fractions were calculated. Experimental data indicated that hydrogen temperatures dropped well below the triple point during testing and were continuing to trend downward prior to system shutdown. Sub-triple-point temperatures were seen to evolve in a time-dependent manner along the length of the horizontal, cylindrical vessel. The phenomenon was observed at two different fill levels.

#### 5.16.2.2 Heat Transfer to Slush Hydrogen

Heat transfer to slush hydrogen was measured in a small laboratory apparatus [697]. Four types of tests were conducted using three different orientations of the heater surface. The four test types were: **(1)** heat transfer at 1 atm pressure in liquid at the normal boiling point temperature, **(2)** heat transfer at the triple-point pressure in liquid hydrogen, **(3)** heat transfer at the triple-point pressure in settled slush hydrogen (estimated solid fraction of 0.45), and **(4)** heat transfer in settled slush hydrogen at 1 atm pressure using helium as the pressurizing gas. The three orientations of the surface were horizontal facing up, vertical, and horizontal facing down.

Densification (subcooling) of liquid hydrogen and oxygen propellants offers potential reductions in size and mass of space launch vehicles. Oxygen densification is easily accomplished by heat exchange with a bath of boiling liquid nitrogen. Parahydrogen presents a more difficult problem because the cooling bath temperature is limited by its 13.8 K triple-point value. To achieve a high degree of densification, the parahydrogen cooling bath must be held close to its triple point and the heat exchanger exit  $\Delta T$  must be small. A parahydrogen heat exchanger was designed to remove approximately 60 kW from a 0.8165 kg/s (1.8 lb/s) flow with an exit  $\Delta T$  of 0.6 K with respect to a bath held at 14.4 K or lower [698]. Test results were compared with design model predictions.

Nucleate boiling heat transfer characteristics of slush hydrogen and slush nitrogen were studied by visual observation of heat transfer states using a heat transfer unit that was placed in a glass Dewar designed to minimize the heat loss from an atmospheric environment [699]. The heat transfer unit used was a circular flat plate 2.5 cm in diameter made of electrolytic copper. During testing, three different orientations of the heat transfer surface were used: horizontal facing up, vertical, and horizontal facing down. Heat transfer data for the normal boiling point of liquid hydrogen and the triple point of liquid hydrogen were obtained up to the critical heat flux (burnout). These data for slush hydrogen and nitrogen, including the results of observation of the heat transfer surface were compared. This provided data for the nucleate boiling heat transfer characteristics of slush hydrogen and slush nitrogen.

A numerical model was built based on the Eulerian model and the kinetic theory of granular flow to investigate the hydraulic and heat transfer characteristics of slush

hydrogen in a circular pipe under both terrestrial and microgravity conditions [700]. The numerical model was validated by experimental results reported in the literature. The flow of slush hydrogen with different inlet velocities and solid fractions was numerically studied to investigate the solid fraction distribution and particle velocity profile (lag) of the outlet cross-section. Considering the transportation of slush hydrogen in practical applications, the hydraulic characteristics of slush hydrogen in an inclined pipe under terrestrial conditions and in a horizontal pipe under microgravity were investigated. The results showed significant influence of the gravity on the solid fraction distribution and pressure drop of slush hydrogen. The heat transfer of slush hydrogen showed that the temperature of fluid can be locally decreased sufficiently using slush hydrogen such that the vaporization of liquid hydrogen can be suppressed. Solid hydrogen particles with small diameters can improve heat transfer between the solid phase and liquid phase, and the melting of solid hydrogen is accelerated. This explains that the increases of both the inlet velocity and solid volume fraction have positive effects on an increase of the local heat transfer coefficient.

### 5.16.2.3 Rheologic and Flow Properties of Slush Hydrogen

The heat of fusion, density, and thermal conductivity of solid  $p\text{-H}_2$  and thermal conductivity of liquid  $p\text{-H}_2$  were determined experimentally to pressures of several hundred atmospheres [100, 652]. Experiments were also carried out on the extrudability and hardness of solid  $p\text{-H}_2$ , heat capacity of solid  $p\text{-H}_2$  calculated over the temperature range 0–15 K and at pressures up to 400 atm. The enthalpy was calculated at saturation and along the melting line.

The pumping characteristics of slush hydrogen were investigated with a SATURN S-IVB liquid hydrogen chilldown pump [701]. As would be predicted from theory, pump performance and cavitation for slush and liquid hydrogen are the same when the difference in fluid density was considered. No pump wear or damage could be attributed to operating the pump with slush instead of liquid hydrogen. A nuclear radiation attenuation densitometer was installed on the 450-L slush generator. The precision of the densitometer was comparable to the accuracy of the pycnometric density determination methods to which it was compared. Flow data were taken in the flow loop for triple-point liquid and slush hydrogen.

The friction losses determined from flow data with hydrogen slush were compared to losses predicted for Newtonian fluids [670]. Liquid-solid mixtures of hydrogen with solid fractions of 0.5 were transferred through three types of flow restrictions, a globe valve, an orifice, and a venturi and the developed head, efficiency, cavitation constant and net positive suction head were measured. When pumped through a pipe network, slush hydrogen behaves as a conventional Newtonian fluid [697, 702–704].

Slush hydrogen was intended to be used as fuel in the National Aerospace Plane, where it would be recirculated in the tank to keep the solids in suspension and pre-

vent them from settling during the launch preparations and the countdown [705, 706]. As part of the National Aerospace Plane Project, an analytical model was developed to perform heat transfer and fluid dynamics calculations for in-line transfer of hydrogen slush [707]. This code, called FLUSH, calculates pressure drop and solid fraction loss for the flow of slush hydrogen through pipe systems. The model can solve the steady-state, one-dimensional equation of energy to obtain slush solids loss by melting estimates. Sample results showed the anticipated degradation of slush hydrogen solid content for various piping systems.

A series of 14 pressurization and expulsion tests were performed with triple-point and slush hydrogen in a horizontally positioned 1.9 m<sup>3</sup> (500 gallon) cryogenic tank [708]. The tank was instrumented to determine temperature distribution in the ullage gas and liquid/slush. The pressurization gas was nominally 80 K gaseous helium (GHe) and/or 300 K gaseous hydrogen (GH<sub>2</sub>). The test results showed that there were marked differences in pressurization performance between GHe and GH<sub>2</sub>, and with liquid or slush hydrogen. Pressurization of slush hydrogen with warm GH<sub>2</sub> was much more rapid and efficient than with cold GHe. In addition, GHe pressurization of slush hydrogen took twice as long as pressurization of triple-point hydrogen, while GH<sub>2</sub> pressurization of triple-point and slush hydrogen took about the same time. Pre-pressurization and expulsion pressurization using GH<sub>2</sub> resulted in substantial ullage pressure collapse at initiation of expulsion (possibly due to surging in the warm outflow line leading to interface disruption and ullage condensation). Conversely, pre-pressurization with cold GHe, followed by expulsion pressurization with warm GH<sub>2</sub>, appeared to suppress GH<sub>2</sub> condensation and eliminate ullage pressure collapse at expulsion. The test data were correlated using a multi-node one-dimensional pressurization/stratification computer code which accounts for real fluid properties, ullage/liquid condensation/evaporation, stratification and heat transfer [661, 709, 710].

If it is too difficult to pump slush hydrogen, slush hydrogen can be pressure-fed to the engine instead. The pressurization gas requirements for expelling slush hydrogen from a storage tank were calculated [711]. A multi-dimensional computational model of the pressurization process in a slush hydrogen propellant storage tank was developed and its accuracy evaluated by comparison to experimental data measured for a 1.5-m (5-ft) diameter spherical tank. The fluid mechanic, thermodynamic and heat transfer processes within the ullage were represented by a finite-volume model. The heat and mass fluxes at the ullage boundary were computed in auxiliary analyses and specified as input to the finite-volume model. Predictions by the model were shown to be in reasonable agreement with the experimental data.

Numerical simulations have been performed using the STAR CD numerical code in order to study the thermofluidynamic behavior of slush hydrogen in straight ducts [712]. For simplicity of the modeling, three straight ducts of same length but different diameter were selected for the simulations. A solid fraction of 35% was

assumed for slush hydrogen. This lower value had to be chosen in order to not override the code's upper limit for a single numerical cell. The analysis performed was mainly aimed at the solid fraction loss due to melting and at pressure drop. The results of the analysis for the solid fraction loss have been compared with the results obtained by previous simulations using FLUSH as numerical code, while the results for the pressure drop have been compared with the results obtained applying the Darcy-Weisbach equation.

The observation of a slight fluctuation in the distribution of solid hydrogen particles in slush hydrogen, i.e., slush hydrogen density, led investigators to place capacitance-type densimeters at two locations along the piped flow to measure the density and to detect density fluctuations [713, 714]. The flow velocity was calculated from the densimeter distance and delay time when the cross-correlation function of the two density signals was at a maximum. This capacitance-type flowmeter has no moving mechanical parts and no probe in the flow stream. A prototype slush hydrogen capacitance-type flowmeter was developed, built, and the accuracy of its output was confirmed by other flow measurements.

Slush hydrogen flowing at low-flow rates has a higher viscosity than the liquid; however, at higher velocities it approaches the viscosity of neat liquid. For the entire range of natural convection and nucleate boiling, the heat transfer at the triple-point temperature and pressure is nearly the same for the liquid and slush [669].

The use of slush in propulsion systems, its flow in pipes and orifices, the design of slush capable turbopumps and injection of slush into combustion chambers require a complete understanding of the flow properties of slush hydrogen [715, 716]. Numerical modeling tools for supporting future technical activities, the development of models of hydrogen slush flows has been split in two parts: the simple engineering model for slush flows in straight pipelines and the development of more complex models. The different issues in terms of modeling related to slush hydrogen have been identified and a potential model for future computational fluid dynamics calculations has been selected.

A three-dimensional numerical simulation code (SLUSH-3D), including the gravity effect based on a thermal non-equilibrium, two-fluid model was used to describe the flow and heat-transfer characteristics of cryogenic slush fluids in a horizontal circular pipe [717]. The calculated results of slush nitrogen flow predicted using the numerical code were compared with experimental results. As a result of these comparisons, the numerical code was validated, making it possible to analyze the flow and heat-transfer characteristics of slush nitrogen with sufficient accuracy. The numerical results obtained for the flow and heat-transfer characteristics of slush nitrogen and slush hydrogen clarified the effects of the pipe inlet velocity, solid fraction, solid particle size and heat flux on the flow pattern, solid-fraction distribution, turbulence energy, pressure drop and heat-transfer coefficient. The differences of the flow and heat-transfer characteristics between slush nitrogen and slush hydrogen were caused

to a large extent by their thermo-physical properties, such as the solid-liquid density ratio, liquid viscosity, and latent heat of fusion.

A numerical simulation based on a finite-volumes discretization using the software library OpenFOAM was carried out on solid-liquid multi-phase flows (slurry) and slush flows inside a typical pipe geometry, very common in propulsion pipelines [718]. A benchmark in comparison with previous experiments and simulations was established to assess the degree of accuracy of the code in predicting pressure drops and solid phase fraction dispersion. The study included the effects of particle size, inlet velocity, and particle concentration on heat transfer and fluid dynamics.

A two-phase mixture was modeled using a separated flow model in which the mathematical equations were written separately for each phase where different properties and velocities are considered for each phase [719]. Mass, momentum, energy equations, and interfacial phenomena equations were developed with the inclusion of drag force, virtual mass force, mass and momentum transfer, and interfacial shear stress. Turbulence effects were treated and multi-particle drag correlations were included. Results for pressure drop across a 38-mm (1.5-in.) Schedule 5S vacuum-jacketed pipe showed good agreement when comparing them with earlier experimental data.

An improved three-dimensional numerical model based on Euler-Euler two-fluid model has been built to predict the flow characteristics of slush hydrogen in a horizontal pipe [720]. In this model, an effective viscosity of mixture, which takes the particle shape and size into consideration, is adopted to modify the drag law for interphase momentum exchange, and the wall boundary conditions for the solid phase are based on Johnson-Jackson model which involves the friction and collision between the particle and the wall. The performance of the model has been validated by a comparison between the calculated results and experimental data from the literature, and it is now considered to be effective for calculations of slush hydrogen flow. The improved model was used to analyze the effects of inlet velocity, solid fraction, and particle size on the flow characteristics, including pressure gradient, solid volume fraction distribution, and velocity distribution. The numerical results indicated that the pressure drops for subcooled liquid hydrogen, under some operating conditions, can be greater than those of slush hydrogen, for which data can be found in some published experimental work.

A numerical model was developed based on the kinetic theory of granular flow to investigate the hydraulic and heat transfer characteristics of slush hydrogen flows in a circular pipe under both terrestrial and microgravity conditions [700]. The numerical model was validated by experimental results reported in the literature. The flow of slush hydrogen with different inlet velocities and solid fractions was numerically studied to investigate the solid fraction distribution and particle velocity profile (lag) of the outlet cross-section.

### 5.16.3 Mission Analyses for Missions Enabled by Slush Hydrogen

Using slush cryogenics instead of saturated liquid at the normal boiling point, cryogenics can be mission enabling or mission extending. The ability of slush and subcooled cryogenics to absorb and tolerate more heat leakage input can enhance space vehicle design and operations through: **(1)** increased storability for long-term missions; **(2)** reduced tank insulation (quantity or quality); **(3)** reduced tank venting frequency and **(4)** reduced tank size and operating pressure [721].

The potential benefits of using densified hydrogen have been quantified for Earth-to-orbit transportation vehicles (space shuttle STS) and space shuttle cargo (STS-C), space exploration mission transfer vehicles (lunar outpost missions), and cryogenic depots in low-Earth orbit. A mission analysis study was performed to quantify the benefits of using slush hydrogen instead of normal boiling-point liquid hydrogen as a fuel for several types of space missions [722]. Vehicles considered in the study included the Space Shuttle/Shuttle-C, LEO to GEO transfer vehicles, Lunar and Mars transfer vehicles, and cryogenic propellant depots in low Earth orbit. The advantages of using slush hydrogen were expressed in terms of initial mass savings at a constant payload, payload differences at a constant tank volume, and increases in fuel storage time for cryogenic depots. Both chemical oxygen/hydrogen and hydrogen nuclear thermal rocket propulsion were considered in the study. The results indicated that slush hydrogen offers the potential for significant decreases in initial mass and increases in payload for most missions studied. These advantages increase as the mission difficulty or energy increases. See also [723,724].

### 5.16.4 In-Space Evaporation Losses and Their Impact on Mission Profiles

For flight tanks which store liquid hydrogen for several hours in outer space, the weight of the insulation becomes a significant burden. One has to optimize the increased thickness and weight of the insulation versus the reduction of evaporative losses. Design properties of various insulations were already summarized in Section 4.4. Now it comes to the point where the optimum amount of insulation has to be determined to minimize evaporative losses with a minimum weight penalty of the dry weight of a spacecraft.

Storability studies of liquid hydrogen and mission analyses have been performed for Earth orbit [725, 726], for trans-Mars orbits [727], for Mars sample return missions [728] and for other space operations. The rate of propellant loss by evaporation and venting depends on the quality of insulation, the albedo of the surface, and the intensity of solar radiation [729–731]. Evaporation losses during space flight can be reduced by optimizing the thickness of multi-layer insulation [732].

## 5.17 Gelled Hydrogen

Gelling hydrogen would reduce sloshing during launch vehicle motions and would allow the suspension of specific impulse-increasing metal additives (lithium, beryllium) or metal hydrides (lithium hydride, beryllium hydride, aluminum hydride) in the liquid fuel. Finely divided, atomized frozen methane could be used as a gelling agent and it would contribute to the heating value of the fuel.

Lithium metal and lithium borohydride were prepared by several methods in the form of ultrafine particles suitable for gelling liquid hydrogen. Lithium-gelled hydrogen and lithium borohydride-gelled hydrogen produced a storable liquid hydrogen gel [733, 734]. A gel was obtained at 61 mass-% (17 vol.-%) lithium. Repeatable yield stresses of about 1250 dyn/cm<sup>2</sup> and shear stresses of about 1400 dyn/cm<sup>2</sup> at a shear rate of 1000 cm<sup>-1</sup> were obtained. Gelled liquid hydrogen was cold-flowed through test components with negligible restrictions due to gellant deposition under normal operating conditions. Liquid hydrogen gels based on lithium were stable to moderate levels of shock and vibrational acceleration. Another gel contained 58.8 mass-% (13.3 vol.-%) LiBH<sub>4</sub>. Another gel was prepared using pyrogenic ("fumed") silica as the gelling agent. The gel formed with 36.1 mass-% SiO<sub>2</sub> had a yield stress greater than 500 dyn/cm<sup>2</sup>.

Gelling of slush hydrogen with pyrogenic silica was accomplished with solid fractions from 0 to 0.2 [670]. The amount of gelling agent required to gel slush was found to be proportional to the liquid volume of the slush. One method for reducing the amount of gelling agent was found in the gelation of slush hydrogen, since only the liquid portion of the slush requires a gelling agent. Gelled slush combines most of the desirable features of both gel and slush. The semi-solid fluid has a high density [735, 736]. Alkoxides and silica were tested as gelling agents for suspending aluminum metal particles in liquid hydrogen and liquid hydrocarbons [737].

A mixture of gelled liquid hydrogen and solid methane has a mixture density approximately two times that of liquid hydrogen alone [738]. This increase in density is partially offset by a loss in  $I_{sp}$  of about 8%, compared to that of liquid hydrogen alone, with liquid oxygen. Increased fuel density reduces fuel tank size, mass and aerodynamic drag.

## 6 Equipment for Use of Liquid Hydrogen

### 6.1 Spark-proof Electrical Equipment in Liquid Hydrogen Storage Areas

Electrical equipment in areas where liquid hydrogen is stored and transferred must be spark-proof. The requirements for hydrogen atmospheres are more stringent than those for other flammable atmospheres because hydrogen can diffuse through many membranes and gaskets that are impermeable to larger hydrocarbon molecules [739].

## 6.2 Liquid Hydrogen Flight Tanks

### 6.2.1 Liquid Hydrogen Flight Tanks for Launch Vehicles

The design of flight tanks has to satisfy special requirements with respect to mass, rigidity, and thermal insulation. The design criteria are a compromise between tolerable evaporation losses and the allowed and affordable thickness and mass of thermal insulation [740, 741].

For upper stages of launch vehicles, it is important to know how long liquid hydrogen can be stored before the rated operating pressure is exceeded and gas must be vented. If the ullage is too small, the vent point will be reached too soon. If the ullage is larger, one is wasting valuable space that could be occupied by propellant. Aerodynamic heating during the first stage operation and the traverse of the lower, denser atmosphere makes this condition worse. Evaporation losses prior to ignition of the second (or upper) stage engine can be calculated from a detailed computer model. Insulation in upper stages is at a premium, so it is economically acceptable to use the more expensive superinsulation for upper stage tanks with cryogenic propellants [742]. The magnitude of tolerable heat flux, avoidance of stratification and the choice of insulation determine the design of flight tanks for liquid hydrogen [743].

### 6.2.2 Surface Tension Propellant Management Devices for Liquid Hydrogen

Surface tension Propellant Management Devices (PMDs) are also called Liquid Acquisition Devices (LADs). Hydrogen has a very low surface tension and thus it is difficult to contain it in a screen basket in low-g environments [744, 745].

The pores in the wire mesh have to be very small to effectively retain the liquid hydrogen in locations where it is supposed to be at the moment when the engine starts firing again. A multi-burn upper stage can afford to fire its small RCS thrusters for propellant settling before re-igniting the engine(s), but an orbital propellant depot is supposed to remain in a pre-assigned orbit and needs other methods for propellant management, such as surface tension screens. Different types of wire mesh weave patterns have been evaluated for this purpose [746]. Results indicated that a  $450 \times 2750$  Dutch Twill mesh may be the optimal screen weave for a future LH2 orbital fuel depot.

The  $325 \times 2300$  mesh screen has a bubble point of 6.1 kPa (46 mm Hg = 24.5 inches of water) in isopropyl alcohol, 2.6 kPa (20 mm Hg = 10.7 inches of water) in liquid nitrogen and 0.46 kPa (3.4 mm Hg = 1.83 inches of water) in liquid hydrogen [747]. These values were in good agreement with results reported in the literature.

The main criterion in designing surface tension propellant acquisition devices is the bubble point under varying gravitational conditions. Surface tension screen development tests will measure the bubble point pressure with different fluids [748]. Test parameters typically include the screen mesh size, type of liquid cryogen, liquid temperature and pressure, and type of pressurant gas. Bubble point data were collected using three fine mesh 304 stainless steel screens in two different liquids (hydrogen and

nitrogen), over a broad range of liquid temperatures and pressures in subcooled and saturated liquid states, using both a non-condensable (helium) and autogenous (hydrogen or nitrogen) gas pressurization scheme. Bubble point pressure scales linearly with surface tension but does not scale inversely with the fineness of the mesh. Bubble point pressure increased proportional to the degree of subcooling. Higher bubble points were obtained by using non-ondensable pressurant gases over the condensable vapor.

Higher bubble points are achieved by using a finer mesh screen and pressurizing and subcooling the liquid with gaseous helium [749]. Once a bubble point pressure is exceeded and control of the whereabouts of the propellant blob is lost, the reseal pressure can be measured that will allow the liquid to re-enter the screen cage [750].

An experiment was carried out that provided measurements of the velocity and pressure fields in a screen channel LAD and compared to the predictions of a hydrodynamic model, which accounts for non-uniform injection through the screen [751].

A passive zero boil-off hydrogen storage system for extended space missions was designed without good thermal insulation system around the liquid hydrogen tank, and it would allow the radiation heat to leak into the space environment from the tank [752]. The theories of heat conduction and radiation heat transfer have been utilized to study the rate of heat absorption for a hydrogen storage tank in space. The model has been simplified by taking several aspects of heat transfer into account, which contains the radiation heat into the storage tank from the sun and spacecraft, the radiation heat into the space environment from the tank, the heat conduction into the tank from the support structure, and the heat conduction into the tank from the liquid oxygen tank. By establishing the function relationship between the rate of heat absorption and the temperature of the liquid hydrogen and oxygen tank, it was theorized that liquid hydrogen can be stored for 2 years without evaporation losses.

### 6.2.3 Liquid Hydrogen Flight Tanks for Airplanes

Liquid hydrogen is being evaluated as the fuel for air-breathing scramjets (Hyper-X and X-43) or even conventional jet engines in commercial transports. Lockheed-Martin P-3 Orion is a four-engine turboprop anti-submarine and maritime surveillance airplane considered for conversion to operation on liquid hydrogen [753]. The fuel tank would take up 65% of the aircraft's internal volume. Despite the large LH2 tank weight, due to the low fuel weight the aircraft's take off gross weight would be only 80% of the current petroleum-fueled P-3. Hydrogen is used as the fuel in fuel cells for electrically driven UAV airplanes that have established record times for staying aloft. Development of liquid hydrogen tanks that were to be flown in aircraft testing ramjets and scramjets started already in the 1950s, but it has not yet led to widespread use of this fuel in air-breathing flight vehicles [754].

### 6.3 Transportation and Transfer of Liquid Hydrogen

Transportation of hydrogen within the USA. on interstate highways is governed by 49 CFR Subtitle B, Volume 2, Chapter 1, Parts 171–180 Hydrogen, specifically 49 CFR Part 173.306, Part 173.316 and Part 173.318.

In anticipation that hydrogen will one day play a major role in the energy sector of industrialized nations, the infrastructure for hydrogen transportation and transfer is already beginning to take shape [45]. As of 2003, there were already ten hydrogen liquefaction plants in North America. Train size ranged from 6 to 35 TPD (5400–32000 kg/day). This is another example where space technology, once derogated as a waste of taxpayers' money, is transferred to use by the general public to the benefit of society.

### 6.4 Trade-off between Pipelines versus Tank Cars

Short-distance transfer operations of liquid hydrogen within tank farms or from a tank farm to an adjacent test or launch site will usually be made by pipelines. But if the production and use point are further apart, of the order of 3–10 km, there comes a point where it is more economical to transport liquid hydrogen by tank car instead of building and maintaining a pipeline. Obviously, the breakeven point depends on the total volume of liquid hydrogen that must be moved and how frequently the pipeline is used. A mathematical method has been developed that would allow the logistics planner to decide between pipeline transport and tank car transport [755]. For best results in a cryogenic pipeline, high vacuum is used as the insulation in the annulus between two concentric tubes with the cold fluid flowing through the center tube [616].

The petroleum processing industry has a network of hydrogen gas pipelines which extends over hundreds of miles. There are already 245 miles of hydrogen gas pipelines connecting refineries in the US. But a network of liquid hydrogen pipelines has not yet been realized or even planned. A design for an LH2 pipeline was based on a single-phase flow regime of LH2 with a certain degree of supercooling [756]. A design for a 200-m long transfer line of LH2 service was calculated. Vacuum-jacketed, double-walled pipelines for liquid hydrogen are expensive to build and would only be used for short distances [757].

Tank cars for transportation of liquid hydrogen come in different sizes. A frequently used rail tank car used to hold 107000 L. The internal container had a diameter of 2.71 m, a length of 20.4 m, was made of stainless steel and surrounded by a 2.54-cm thick insulating double-walled layer that was evacuated to below 0.013 Pa ( $10^{-4}$  mm Hg). The evaporation losses from a railroad tank car like this were approximately 0.3%/day (without any contributions by *o-p* conversions). Liquid hydrogen has been transported in such railroad tank cars all across the American continent [758].

**Figure 63:** Liquid hydrogen tanker truck. (Photo: courtesy of Linde Gas Division-Hydrogen Solutions)

For transport by road tank cars holding 29500 L liquid hydrogen have been used and are still being used (Figure 63). Evaporation losses from these tank cars are 0.5%/day.

The quick dispersion of the boil-off from these tank cars is a critical problem. The escaping gas has to be diluted quickly to avoid formation of explosive gas clouds in the vicinity of the tank car. The tank car is under a slight overpressure and the gas is released through a relief valve. Instead of venting the gas directly, it passes through a small turbine which drives a fan which aspirates an airstream that dilutes the vented hydrogen quickly to below 2 vol.-% to below the lower flammable limit.

At one time in the early 1960s there was a smaller tank car on the road which held 6000 L and had evaporation losses of the order of 1.7%/day [759]. There are smaller tanks holding 1000 L available that can be skid-mounted and moved by a fork lift. The evaporation losses from a small tank like this are typically 1%/day. The insulation of one type of these containers was of the SI-62 type.

## 6.5 Transfer and Pumping of Liquid Hydrogen

Ground service equipment for fueling of rockets with liquid hydrogen depends on reliable transfer procedures between the stationary supply tank and the vehicle standing on the launch pad [501].

Liquid hydrogen ground service facilities for the SATURN-C1 rocket were thoroughly tested before the first flight vehicle was loaded with liquid hydrogen [760]. Liq-

liquid hydrogen can be transferred by pressurization or by pumps. Gravity-fed transfer is rarely used (at least there are no published designs).

### 6.5.1 Pressure-fed Transfer of Liquid Hydrogen

Only two gases can be used for pressure feeding hydrogen from pressurized tanks: warm hydrogen and helium. If warm gas pressurization is used, the entry points in the ullage need to be through multiple diffusers so that the hot gas does not impinge on the liquid surface and cool down, increasing the pressurization gas requirements [761].

Warm hydrogen for pressurization of liquid hydrogen tanks can be stored in compressed gas cylinders or can be generated *in situ* by evaporating some liquid hydrogen in a vaporizer. If helium is used as a pressurant gas for liquid hydrogen, one must consider that helium is partially soluble in liquid hydrogen [762, 763].

The solubility of helium in liquid hydrogen at 17.4, 20.39, and 21.8 K, and pressures of 2.9–32 atm (43–475 psia) is summarized in Table 47.

**Table 47:** Solubility of helium in liquid hydrogen.

| Temperature, K | Pressure, atm | Liquid phase  |                 | Gas phase     |
|----------------|---------------|---------------|-----------------|---------------|
|                |               | Helium, mol-% | Hydrogen, mol-% | Helium, mol-% |
| 17.4           | 3.36          | 0.20          | 99.80           | 83.5          |
| 17.4           | 5.64          | 0.22          | 99.78           | 89.7          |
| 17.4           | 6.52          | 0.27          | 99.73           | 91.0          |
| 17.4           | 9.60          | 0.45          | 99.55           | 93.5          |
| 17.4           | 14.1          | 0.74          | 99.26           | 94.6          |
| 17.4           | 21.5          | 1.08          | 98.92           | 95.1          |
| 20.39          | 4.28          | 0.59          | 99.41           | 73.7          |
| 20.39          | 12.0          | 1.53          | 98.47           | 87.3          |
| 20.39          | 15.1          | 2.04          | 97.96           | 88.9          |
| 20.39          | 17.4          | 2.16          | 97.84           | 89.6          |
| 20.39          | 20.8          | 2.48          | 97.52           | 90.0          |
| 20.39          | 24.4          | 2.77          | 97.23           | 90.0          |
| 20.39          | 26.9          | 3.01          | 96.99           | 90.0          |
| 20.39          | 27.6          | 3.06          | 96.94           | 90.1          |
| 20.39          | 32.3          | 3.44          | 96.56           | 90.1          |
| 21.8           | 2.92          | 0.18          | 99.82           | 60.8          |
| 21.8           | 5.57          | 0.29          | 99.71           | 73.4          |
| 21.8           | 10.7          | 1.36          | 98.64           | 83.3          |
| 21.8           | 15.4          | 1.49          | 98.51           | 87.9          |
| 21.8           | 20.8          | 2.44          | 97.56           | 88.2          |
| 21.8           | 26.2          | 3.06          | 96.94           | 88.3          |

Data source: [764,765]

The measured 1952 data were not in agreement with thermodynamic theories. It took a new approach incorporating the fugacity of hydrogen to derive a set of equations that was in agreement with the measured data [765]. See also [268].

The helium effect on the pressurization behaviors of cryogenic propellant tanks was represented by an enhanced computational fluid dynamic (CFD) approach, which could simultaneously account for the species transfer as well as its effect on phase change [766, 767]. Two transient pressurization events, including depressurization after an active helium pressurization and pressurized discharge process, were selected as examples, and the pressure responses, species concentration distribution, as well as mass transfer rates were analyzed. The results showed that the influence of species transfer on pressure behavior is strongly related to the pressurization time. For the depressurization performance after a pre-pressurization operation, the residual helium leads to a continuous liquid evaporation in the depressurization, while a pure hydrogen case experiences a vapor condensable process. The helium and hydrogen could sufficiently diffuse into each other within the depressurization period. For a typical pressurized discharge process, the species diffusion affects the distribution to a certain degree but a weak influence on the general pressurization performance remains. The species concentration along radial direction of the tank caused a distinguishable radial temperature gradient.

### 6.5.2 Pressurant Gas Requirements for Pressurized Transfer of Liquid Hydrogen

Because the only possible pressurant gas (other than hot hydrogen) for pressurized transfer of liquid hydrogen is helium, the pressure in a freshly pressurized tank decays because the gas cools off and because some of the helium gas dissolves in liquid hydrogen. The density and other properties of liquid hydrogen change as the result of dissolved helium contained in it. Therefore, it is important to have knowledge of the solubility, rate of diffusion and pressure-temperature-density behavior of the hydrogen/helium system. The solubility of helium in liquid hydrogen was already described in this book in Section 2.16.2. The PVT-X and  $P\Delta T$ -X phase behavior of helium/hydrogen mixtures was already described in Section 2.16.2.

The pressurant gas consumption for pressure-feeding of cryogenic liquids can be calculated using a variety of different equations. Table 48 is a summary of literature on pressurant gas requirements.

If the pressurant gas hydrogen is preheated, there is a 0.8% reduction in pressurant gas requirements for each 5.5 K increase in pressurant gas temperature [782]. The use of a straight-pipe injector decreased the pressurant gas requirements by 9 to 35% compared to that of a diffuser-type injector. Pressurization efficiency depends on the extent of gas mixing in the ullage. The gas mixing depends on the type of injector. Certain types of injectors can reduce the gas-wall heat losses and improve the performance of heated gas pressurization systems [783].

**Table 48:** Summary of literature on pressurant gas requirements.

A double-walled 2360-L tank insulated with a powder/vacuum jacket and instrumented with a liquid level sensor, a range of pressure gauges and numerous thermocouples was used to measure pressurant gas requirements for transfer of liquid hydrogen. The thermocouples gave a spatial profile of vertical and horizontal temperature gradients in a tank after it was pressurized [559, 784]. Following pressurization, the liquid may stratify and the temperature of the liquid gradually rises. The hotter, upper layer may feign a higher vapor pressure when in reality the bottom liquid is still cold. It takes a while until the temperature of the stagnant liquid at the interface to the gas space and in the bulk of the liquid has equilibrated. During this time, temperature differentials can cause thermal stresses in the container wall material.

A multi-dimensional computational model of the pressurization process in a liquid/slush hydrogen tank was developed and used to study the influence of heat flux rates at the ullage boundaries on the process [785, 786]. The model computed these rates and performed an energy balance for the tank wall, whereas previous multi-dimensional models required *a priori* specification of the boundary heat flux rates. Analyses of both liquid hydrogen and slush hydrogen pressurization were performed to expose differences between the two processes. Parameters of interest are the ullage boundary heat flux rates and pressurant mass flow rate. Detailed velocity fields and temperature distributions were presented for selected cases to further illustrate the pressurization process. It was demonstrated that ullage boundary heat flux rates do significantly effect the pressurization process and that minimizing heat loss from the ullage and maximizing pressurant flow rate minimizes the mass of pressurant gas required to pressurize the tank. Additional information on pressurized transfer of liquid hydrogen can be found in [787, 788].

### 6.5.3 Pressurization to Increase Net Positive Suction Head of Liquid Hydrogen in Pump-fed Systems

Low pressure at the suction side of a pump can cause the fluid to start boiling, resulting in reduced energy efficiency, cavitation, and damage to the pump impellers. Boiling starts when the pressure in the liquid drops to below the vapor pressure of the fluid at the actual temperature.

**Cavitation** means **cavities** or bubbles in the liquid. Cavitation is the forming and collapsing of bubbles. Bubbles take up more space than the liquid so the capacity of a pump drops once it starts cavitating. Collapsing bubbles may cause shock waves that can damage the impeller and volute. The violent collapse of cavitation bubbles creates a shock wave that can erode material from internal pump components (usually the leading edge of the impeller) and creates noise and vibrations. Vibration can cause other mechanical failures in the pump and associated equipment. This makes cavitation a problem for both the pump and the mechanical seal.

These problems can be avoided by providing sufficient Net Positive Suction Head (NPSH) at the inlet to the pump. The suction head in the fluid close to the impeller can be expressed as the sum of the static and the velocity head. The suction head is increased by pre-pressurizing the liquid in the supply tank from which it is drawn. For flight vehicles, the gas required to maintain the NPSH while the propellant tank is drained is typically not carried as compressed gas (it would be very heavy to carry compressed gas tanks), but it is generated on board large rockets by vaporizers fed with a side-stream of the liquid to be pressurized [513]. The pressurant liquid fed to these high-pressure vaporizers first has to be boosted by a high-pressure pump [789].

The National Aerospace Plane was designed to use slush hydrogen as the fuel. Pressurization of the fuel tank in preparation for launch would result in some of the pressurant gas condensing on the cold liquid if hydrogen was used for pressurization instead of helium. A multi-dimensional computational model of the pressurization process in a slush hydrogen propellant storage tank was developed and its accuracy was evaluated by comparing it to experimental data measured for a 1.5-m (5-ft) diameter spherical tank [790].

If left undisturbed, the ullage gas would thermally stratify. As part of the National Aero-Space Plane (NASP) project, the multi-dimensional effects of gravitational force, initial tank pressure, initial ullage temperature and heat transfer rate on the 2-D temperature profiles in the tank ullage were studied [791, 792]. These effects were examined on the basis of previous liquid hydrogen experimental data with gaseous hydrogen as the pressurant.

## 6.6 Zero-*g* Transfer of Liquid Hydrogen

Orbital propellant depots will require long-term storage of cryogenic propellants in space and transfer of liquid hydrogen between supply and user tanks under conditions of zero or microgravity [793].

The problem of the expulsion of liquid cryogenics from a partially filled orbital depot tank involves tracking the motion of a floating, mobile and expanding vapor ullage as fluid is expelled from a tank. A simulation of the interface movement of the vapor ullage in a volume of confined liquid under zero gravity was carried out by solving the Navier-Stokes equations in the transformed boundary-fitted curvilinear co-ordinate system using a finite difference approach [794].

A thermal model of an orbital propellant depot was used to examine the effects of passive and active thermal management strategies [795]. Results showed that an all-passive thermal management strategy would result in significant boil-off for both hydrogen and oxygen. Zero boil-off of propellant is achievable only with the use of active cryocoolers; however, the cooling power required to produce zero boil-off is an order of magnitude higher than current state-of-the-art cryocoolers. The study showed a zero boil-off cryocooler minimum power requirement of 80–100 W at 80 K for liquid oxygen, and 100–120 W at 20 K for liquid hydrogen.

A CFD model, verified by experimental data, is capable of accurately simulating the no-vent filling process with good flexibility [796]. No-vent filling processes under different gravities were compared and the effects of four factors including inlet configuration, inlet liquid temperature, initial wall temperature and inlet flow rate, were studied, concluding that: **(1)** compared to the situations in normal gravity, the no-vent filling in microgravity experiences a more adequate liquid-vapor mix, which results in a steadier pressure response and better filling performance. **(2)** Inlet configurations seem to have negligible effects on the no-vent filling performance under microgravity since liquid could easily reach the tank wall and then cause a sufficient fluid-wall contact under any inlet condition. **(3)** Higher initial tank wall temperature may directly cause a higher pressure rise in the beginning. Sufficient precooling and reasonable inlet liquid subcooled degree would assure the reliability and efficiency of the no-vent fill under microgravity.

## 6.7 Liquid Hydrogen Pumps

The design of centrifugal pumps for liquid hydrogen required special technologies, which were developed mostly as an offshoot of the use of liquid hydrogen as a rocket propellant. Similar pumps had to be designed for other cryogenic fluids [797].

### 6.7.1 Liquid Hydrogen Pumps for Flight Vehicles

Lubrication of bearings in liquid hydrogen pumps is very difficult because there are no known lubricants to prevent galling of metal-to-metal rotary seals. It was a major breakthrough when it became possible to lubricate the shafts of liquid hydrogen pumps used on the CENTAUR or SATURN S-IV upper stages with a stream of liquid hydrogen [798]. The shafts were suspended hydrodynamically in flowing hydrogen. Such pumps have achieved very long operating times under cryogenic conditions. Other cryogenic fluid pumps have been using impregnated carbon seals in the shaft seals and bearings [799].

An early model of a liquid hydrogen pump had a flow rate of 2.73 kg/s at 26.5 atm and was spinning at 35000 RPM. The flow rate was not very susceptible to fluctuations in the back pressure [800].

Both propellant pumps in a cryogenic propellant rocket should be able to feed the full flow rate as soon as the start signal is given. This is not quite possible with liquid hydrogen without special prearrangements. Without such precautions, the first hydrogen entering the warm pump would evaporate and two-phase flow would cause low overall pumping. Initially, pumps in the CENTAUR upper stage were flushed for 20–30 s after stage separation and before engine ignition with liquid hydrogen which resulted in a substantial waste of fuel. Later the pumps were pre-cooled with liquid helium on the ground before launch [801]. That reduced the flush time after stage separation by 75%, and the payload could be increased by more than 12.7 kg. Lubricating mechanism, cage design, and heat generation of ball bearings for liquid hydrogen turbopumps were studied [802].

Pressure of liquid hydrogen fed to a vaporizer that generates hydrogen gas for pressurizing propellant tanks while liquid is withdrawn must be boosted by a high-pressure pump [789]. In designing LH2 pumps, the most critical part is the inlet (suction side) of the pump where one must avoid cavitation [803]. Three different helical inducers were tested in liquid hydrogen for their ability to induce or prevent cavitation [804]. The tip helical angles were 78, 80.6, and 84°. The pressure requirements as well as the thermodynamic effects of cavitation for a head-rise coefficient ratio of 0.70 were the greatest for the 84° inducer and least for the 78° inducer for a given flow coefficient ratio. The non-cavitating flow range was the widest for the 78° inducer and the narrowest for the 84° inducer.

A finite element method was used to calculate the transient temperature field distribution during hydrogen pump chilldown in a liquid rocket engine before the engine starts [805]. The chilldown flow rate and chilldown time are both related to the wasteful consumption of liquid hydrogen that is dumped. If the chilldown flow rate or time is not adequate, it may jeopardize the engine start reliability.

### 6.7.2 Liquid Hydrogen Pumps for Ground Service Equipment Low-pressure Transfer

Pumps for transferring liquid hydrogen between tanks on the ground do not have to operate at such high pressures as pumps in rocket engines. They do not have to come up to full operating pressure as fast as pumps in flight vehicles.

Pumps for ground service equipment can even be designed as immersion pumps and thus they are precooled all the time as long as the tank is full. Unlike liquid oxygen, most liquid hydrogen is transferred from storage to propellant tanks by means of pressurization. For higher flow rates, a liquid-hydrogen transfer system was designed based on a Dewar-mounted liquid-hydrogen booster pump [806].

### 6.7.3 Liquid Hydrogen Facility Pumps for Rocket Test Stands

Liquid propellants for rocket engine tests of individual engines as opposed to tethered all-up live stage ground testing is usually done with facility pumps which are more rugged than flight pumps and designed for longer operating times. The test facilities for nuclear-thermal rockets with liquid hydrogen operated by the US Atomic Energy Commission (AEC) required very large pumps, bigger than any liquid hydrogen pumps that had been built up to that time. One of the pumps used by the AEC was driven by a 5000-HP motor and was capable of feeding 27 kg/s at a back pressure of 29.3 atm gauge [9]. Some facility pumps can be used for liquid nitrogen or liquid hydrogen [807].

In order to prevent cavitation in the suction (inlet) side of the pump, the tank is usually pressurized or the liquid is subcooled. Either method will prevent cavitation only for a short time due to continuing heat leaking into the tank [808]. See also [809].

### 6.7.4 Slush Hydrogen Pumps

Extrapolation of relationships for pumping water slurries indicated that the pumping characteristics of liquid and slush hydrogen should be the same when the difference in density is considered [702, 810]. This difference to water slurry pumping behavior is due to the similar flow losses for liquid and slush hydrogen.

### 6.7.5 Gaseous Hydrogen Compressors for Stationary Facilities

Electrochemical compression of hydrogen (and oxygen) is the reverse of high-pressure fuel cells. If additional electrical energy is available, hydrogen can be compressed from atmospheric pressure to higher pressures by feeding it to a fuel cell electrode at moderate pressure, boosting the voltage and discharging it in an electrolyzer at higher pressure [811, 812]. At the same time, hydrogen is purified. The oxygen created at the same time at the opposing electrode can be expanded to lower pressure and recycled.

## 6.8 Liquid Hydrogen Transfer Lines and Pipelines

Sections of double-walled straight pipe can be considered as small tanks with a high L/D ratio with two open ends and often use the same types of thermal insulation. Each section is surrounded by its own separate vacuum jacket. A specification describes low pressure vacuum jacketed pipelines with 1/2-in. through 16-in. diameter and a maximum internal operating/service pressure of 1.9 MPa (275 psig) [813].

The main difficulties with double-walled pipelines are encountered at Ts, bends, and joints. Instead of plain vacuum jackets, pipes are often insulated with powder-filled vacuum jackets. Powder-filled vacuum jackets do not need to be evacuated to the very low pressures required for plain vacuum jackets. Plain vacuum jackets require vacuum of  $10^{-5}$  mm Hg, whereas a vacuum of 0.05 mm Hg suffices for powder-filled insulations [814].

It has also been proposed to fill the jacket with a condensable gas instead of evacuating it. Once the condensable gas (e.g., carbon dioxide) condenses, it creates a vacuum [815]. Such units have the advantage that during idle periods they are not losing their vacuum since no ambient air will leak into the system. There are also couplings for flexible cryogenic lines [816, 817].

Due to large circumferential temperature differentials the thermal stresses in double-walled lines for liquid hydrogen transport during uneven cooldown can be substantial and destructive [818]. A line that initially was straight can distort like a snake. In particular, if the line is not filled to its full cross-section, with only the lower half filled with liquid, the temperature differential between top and bottom is critical and can cause permanent distortions and damage.

The experiences gained and lessons learned during the design of pipelines for the ROVER program were summarized in [819]. They report temperature differentials of up to 230 K between the top and the bottom of large pipelines.

In spite of the low viscosity of the liquid, the pressure drop of liquid hydrogen flowing through a long system of lines can be measurable and has to be figured in the design of plumbing systems, either with single-phase flow [820] or with two-phase flow. In particular, two-phase flow will increase the pressure drop significantly above that of the pure liquid flow [821, 822]. The two-phase flow condition is observed mostly during the cooldown of lines and equipment. Two-phase flow is also called “mist flow” [823]. Rotameters would no longer indicate the true volume flow rate of liquid passing through the line. The quality of the liquid (its unwanted content of bubbles, expressed as the vapor:liquid ratio) can be measured by a measurement of the dielectric constant of the mixture filling a known capacitance flow-through cell [824]. Similar instruments were even used in the heat exchanger inside of a KIWI nuclear reactor to monitor the state of phase change from liquid to gas [825].

Propellant transfer through double-walled plastic hoses has been proposed. The hoses are made from aluminized Mylar [826]. The hoses could be transferred to remote locations (space stations, lunar bases) rolled flat like a fire hose, then inflated

at the point of use and the jacket would be filled with polyurethane foam (similar to polyurethane used for foaming in place of delicate instruments prepared for shipping).

If liquid hydrogen is transferred through uninsulated lines, substantial evaporation losses during cooldown and also during transfer must be taken into account [827]. Short lines between tanks and pumps and pumps and engines in flight vehicles are not always insulated to save weight.

## **6.9 Instrumentation and Equipment for Liquid Hydrogen Service**

Sensors and transducers for use with liquid hydrogen must be qualified to operate at extremely low temperatures and may be subjected to steep temperature transients [828].

### **6.9.1 Fluid Flow Control Components**

The measurement and control of fluid flow and physical properties is an important part of designing either a ground service system or a flight system using liquid hydrogen or any other liquid rocket propellant. Whereas for liquid nitrogen or liquid oxygen systems most components are available off-the-shelf from a variety of vendors worldwide, that is not always the case for liquid hydrogen components. In many cases the components offered are modified variants of components sold for liquid nitrogen or liquid oxygen systems. One may still have to test the components under actual use conditions to make sure they work as intended at the much lower temperature.

During the development phase, there were several closed-loop liquid hydrogen circulation component test sites in use at various places in the US, including those at Pratt & Whitney [829], Aerojet [830], and General Dynamics [831].

### **6.9.2 Valves for Liquid Hydrogen Service**

Valves and pumps have so many moving parts that they are usually not designed with a double-walled jacket for insulation purposes. Many valves have only clamshell-type insulation that is easy to remove when the valve needs to be serviced.

Evaluation criteria for liquid hydrogen are the same as for any other propellant valves. In addition, they should not have a high heat capacity, so that they cool down quickly and do not cause too much boil-off.

#### **6.9.2.1 Flow Control Valves**

Valves of different design types have been used for ground service equipment with liquid hydrogen: Either ball valves or sliding gate or sliding cone valves have been used. Low pressure drop and high flow coefficient are desirable [832]. Ice accumulation along the valve stem may make valve operation difficult at times. Therefore, the

valve stem must be made of a material with low thermal conductivity. While it is relatively easy to block thermal leakage along pipes, valves are likely paths of heat leakage. A foam-encapsulated 10-cm I.D. valve can leak as much as 75 kcal/h. If the same design was surrounded by a vacuum jacket, the heat leak would still run as high as 55 kcal/h. Smaller (5 cm I.D.) valves may have heat leak rates between 33 and 43 kcal/h. Materials selection for valves for liquid hydrogen service is described on pages I-95 through I-97 of [833] and page 3-83 through 3-85 of [834].

#### 6.9.2.2 Pressure Relief Valves

Because of continuous boil-off losses, pressure relief valves are an essential part of liquid hydrogen storage tanks. Ice accumulation must be avoided to keep them in working order [835].

#### 6.9.3 Liquid Level Gauges for Liquid Hydrogen Service

The liquid level in a stationary liquid hydrogen storage tank may be difficult to determine while the liquid is boiling and sloshing around. Floats cannot be used for liquid hydrogen level sensing because liquid hydrogen has such a low density. Sight glasses are out of the question because they would ice up within seconds.

Electric capacitance measurements are being used for liquid level sensing both in LOX and in LH<sub>2</sub> service installations. They measure the difference of the dielectric constant for the liquid phase and the gas phase. There are at least two different designs: one consists of a long capacitor where the fluid fills the space between the electrodes to give a continuous readout proportional to the liquid level. The other design gives incremental liquid level signals by arranging a large number of small capacitors with individual leads in an array [524].

A capacitive liquid level meter working at low temperatures measured capacitance between parallel electrodes immersed in the liquid [836]. The meter was tested for liquid nitrogen, hydrogen, and helium. The operation was successful using an AC capacitance bridge. The estimated accuracy of the instrument was better than 0.2 mm for liquid hydrogen.

An optical-fiber-based liquid level detection system for applications in cryogenic environment consisted of a multiplexed array of point liquid probes [837]. Two different designs of the probe were fabricated and tested. The multiplexing of multiple liquid probes using an optical time domain reflectometer (OTDR) device was successfully demonstrated.

A sensor consisting of a vertical linear array of 140 highly sensitive optical fiber refractometric transducers with a measurement range of 1.6 m with a resolution of up to 5 mm can be used for measuring the level of any cryogenic liquid, such as liquid oxygen or liquid hydrogen [838].

Other liquid level gauges measure the difference in the thermal diffusivity in the vicinity of a hot wire [839]. The difference is mostly due to the difference in heat ca-

capacity of the two fluids: The heat capacity of liquid parahydrogen at its natural boiling point is  $9.66 \text{ J g}^{-1} \text{ K}^{-1}$ , whereas the heat capacity of gaseous hydrogen a few degrees above the boiling point is  $12.15 \text{ J g}^{-1} \text{ K}^{-1}$ . The liquid : gas ratio of these two properties for hydrogen is 1 : 1.26 whereas the same properties for LOX are  $1.699 \text{ J g}^{-1} \text{ K}^{-1}$  for the liquid and  $0.910 \text{ J g}^{-1} \text{ K}^{-1}$  for the gas, with a gas : liquid ratio of 1 : 1.87, giving a more distinct reading.

Because of continuing boil-off, liquid level measurement is a constantly changing readout. Liquid level gauges are mounted in different positions of both ground service equipment and flight tanks. The upper sensors are supposed to make sure that a flight tank is full enough just prior to launch and to meter in the make-up flow of fresh propellant to replace evaporation losses during the countdown and launch hold [840].

The liquid level measurements based on thermal diffusivity are made with heated platinum wires. The sensor design uses a very fine platinum sensing element tensioned within a ceramic housing and brazed to gold plated contacts. The platinum wire liquid hydrogen level sensors in the Space Shuttle external tank have been the cause of many launch aborts. In spite of the fact that already four multiple sensors were installed for redundancy, quite often more than two of the sensors failed during actual use conditions in spite of the fact that the tank had been tested before it was attached to the stack. Both liquid hydrogen and liquid oxygen systems each utilized four sensors and used the same logic to trigger an engine cut-off. The 13 July 2005 mission STS-114 of Space Shuttle Discovery was scrubbed when a low-level fuel cut-off sensor for the liquid hydrogen tank inside the external tank failed a routine prelaunch check during the countdown, causing mission managers to scrub Discovery's first launch attempt. The sensor protects the Shuttle's main engines by triggering their shutdown in the event fuel runs unexpectedly low (you do not want to operate these engines on a stoichiometric or oxygen-rich mixture ratio). The sensor was one of four inside the liquid hydrogen section of the external tank [841, 842]. Similar problems were encountered during STS-115, STS-121, and STS-122, and the cause was later traced to the connector pins at the feed-through through the tank wall.

Liquid level sensing is more difficult in a zero-g condition in outer space when the liquid is floating around throughout the tank, not knowing where is up or down [843]. In an effort to develop and evaluate zero-gravity propellant quantity gaging system concepts suitable for application to large, on-orbit cryogenic oxygen and hydrogen tankage, 18 potential quantity gaging approaches were investigated for their merit and suitability for gaging two-phase cryogenic oxygen and hydrogen under zero-gravity conditions [844]. These approaches were subjected to a comprehensive trade study and selection process, which found that the RF modal quantity gaging approach was the most suitable for both liquid oxygen and liquid hydrogen applications.

Summaries of liquid level sensing for liquid hydrogen are given in [845–847]. It is difficult enough to measure liquid levels in liquid hydrogen, but it is even more difficult to measure liquid levels in slush hydrogen [848].

Platinum hot wire liquid level sensors were used in an early version of the CEN-TAUR upper stage. In looking for most probable causes of an explosion, the catalytic action of platinum in its ability to ignite oxygen/hydrogen mixtures was blamed for the explosion after suspected air intrusion into the tank. It was attempted to poison the catalytic activity of the platinum wire to eliminate it as a potential source of ignition if air should intrude into the tank again [849].

The testing of liquid-vapor detectors in zero gravity in LH2 was done in a sealed glass Dewar system to eliminate any chance of mixing H<sub>2</sub> and air [850]. Most of the tests were performed with the leads to the sensor horizontal and some were done with rapid cycling when immersing it in LH2.

Most of the instrumentation intended for density measurement of cryogenic liquids can also be used for liquid level sensing [851]. This includes dielectric constant/capacitance, resonant cavity, nuclear radiation attenuation, acoustic reflection, and forced harmonic oscillation.

The Helmholtz resonance technique was applied to a liquid level gauge for liquid hydrogen [852]. A Helmholtz resonator with a small loudspeaker was installed in a glass cryostat. A swept frequency signal was supplied to the loudspeaker, and the acoustic response was detected by measuring the electrical impedance of the loudspeaker's voice coil. The penetration depth obtained from the Helmholtz resonance frequency was compared with the true value, which was read from a scale. There are still certain problems with regards to practical applications of this instrument.

#### 6.9.4 Flow Meters for Liquid Hydrogen Service

The flow of liquid hydrogen can be measured by differential pressure measurement before and behind an orifice, by cavitating venturi or by turbine flowmeters [524]. The difficulty with turbine flow meters is that they are often accidentally overspun during the cooldown of the system when large amounts of gas rush through the lines [853].

The calibration of flowmeters with liquid hydrogen is difficult because of evaporative losses while the measurement is in progress. For calibration of flow meters for non-cryogenic fluids, it is common practice to weigh the mass of the fluid that has passed through the meter. For hydrogen this method is not very accurate because hydrogen weighs only a small fraction of the dry weight of the receiving vessel. Differential weighing methods were developed that were supposed to measure even small weight differences of hydrogen tanks with an accuracy better than  $\pm 0.3\%$ . Calibration of these flow meters can be achieved within  $\pm 0.17$  mass-% or  $\pm 0.28$  vol.-% by the method described in [854].

Many turbine flow meters for other fluids are often calibrated with water at room temperature and the readings are then extrapolated to fluids with other densities and viscosities; however, the dimensions of the flowmeters at room temperature and at operating temperature are quite different due to thermal contraction of all parts [855].

It was attempted to establish a correlation between the readings with water at room temperature and with liquid hydrogen below 20 K. The goal was an accuracy of better than 2%.

Other methods for calibration of flowmeters for liquid hydrogen in use at NASA see [856, 857]. The main difficulty during such calibrations is to maintain a constant liquid flow for a certain time to obtain a reproducible reading. In order to prevent boiling of the fluid in the line, the entire assembly may have to be immersed in a bath of liquid hydrogen. Preliminary tests of an orifice plate and a nozzle indicated that the same correlation of discharge coefficient with Reynolds number applies for liquid hydrogen as for water. Preliminary tests of several commercially available turbine-type meters showed that the calibration constant (pulses per unit volume) for liquid hydrogen may differ on average by about 1.0% from the value for water [858, 859].

A group of 14 turbine-type flowmeters of 2.5 and 4-cm nominal size were operated for 100 or more hours at an average fluid speed in the unobstructed, upstream pipe of 20 m/s for the smaller meters and 9 m/s for the larger meters [860]. Calibration shifts over a 6.1 range of calibration flow rates varied from 0.5 to 1% after 50 h of operation. It was concluded that use of ball bearings with glass-filled Teflon retainers is most likely to produce minimal calibration shift with protracted use. 100 h was recommended, depending on accuracy requirements, for flowmeters used at the fluid speeds of these tests. Other calibration methods for liquid hydrogen flowmeters were described in [861–863].

Venturi orifices can be used to both measure and stabilize the flow of liquid hydrogen. One of the throttleable venturis was capable of regulating liquid hydrogen flow in the range from 34 to 1000 L/min.

Density measurements under flow conditions are generally more difficult than a density measurement in a static tank. A two-phase density meter for the flow case should have a rapid response and a wide range in order to cover both liquid and gaseous hydrogen, and it should also present a minimal obstruction to the flow. A device that possesses these desirable features is an open-ended microwave cavity. The shift in the resonant frequency when a gas is introduced into an evacuated microwave cavity gives a measure of the dielectric constant of the gas. Hydrogen density measurements obtained by using a microwave cavity were taken under **static** conditions. The density of the hydrogen in the vessel was determined by using the microwave cavity to measure the dielectric constant and then computing the density from Böttcher's equation, and by measuring the pressure and temperature of the hydrogen and then using an equation of state for parahydrogen developed by the National Bureau of Standards to compute the density [864, 865]. Resonant frequency measurement systems were used in conjunction with an open-ended microwave cavity to continuously monitor density of liquid hydrogen in a flow system [866, 867].

A prototype slush hydrogen capacitance-type flowmeter was developed, built, and the accuracy of its output was confirmed by other flow measurements. This capacitance-type flowmeter has no moving mechanical parts and no probe in contact

with the flow stream [713, 714]. The flow velocity was calculated from the densimeter distance and delay time when the cross-correlation function of the two density signals was at a maximum.

### 6.9.5 Temperature Sensors for Liquid Hydrogen Service

Temperature measurements are not so critical for liquid hydrogen in a vented storage vessel but are very important for subcooled and slush hydrogen.

The temperature of cryogenic fluids is usually measured with resistance thermometers. A ruggedized system was developed that will, with individual calibration, provide measurement accuracy of  $\pm 0.1^\circ\text{F}$  [868]. Besides metals, also graphite can be used as the conductor in low-temperature resistance gauges [869].

### 6.9.6 Pressure Transducers for Liquid Hydrogen Service

Pressure transducers in liquid hydrogen must be capable of measuring not only static pressures, but also pressure oscillations with response frequencies up to 5 kHz [869, 870].

A summary of pressure measuring instrumentation for cryogenic service is given in [871]. All transducer types of pressure transducers, such as strain gage, capacitance, potentiometric, or piezoelectric, were included and their uses with gaseous or liquid oxygen were reviewed.

## 6.10 Density of Slush Hydrogen Measurement

A hydrogen slush density reference system calibration of field-type instruments was based on the buoyancy principle of Archimedes [872, 873]. The solids were weighed in a low-mass container so arranged that solids and container are buoyed by triple-point liquid hydrogen during the weighing process. Several types of hydrogen slush density transducers, including beta ray attenuation, gamma ray attenuation, capacitance method, microwave method for dielectric measurement and velocity of sound were developed and tested for possible use as transfer standards. The most successful transducers found were those which depend on change in dielectric constant, after which the Clausius-Mossotti function is used to relate dielectric constant and density.

A wide range of instrumentation is available to characterize slush hydrogen during its production, storage, transfer and use [874, 875]. Slush hydrogen density gages intended for the National Aerospace Plane would have had to survive extreme temperatures and needed to be protected from high temperatures during the re-entry phase of the vehicle [876, 877].

As part of a study to demonstrate the suitability of an X-ray or gamma ray probe for monitoring the quality and flow rate of slush hydrogen, mass attenuation coefficients for Cd-109 X-ray and gamma radiation in five chemical compounds were mea-

sured [878]. It was shown that the mass attenuation coefficient for the selected radiations was independent of the phase of the test fluids or phase ratios in the case of mixed phase fluids.

The density of slush hydrogen can be measured by using the phase shift that takes place when microwaves are propagated through slush hydrogen, i.e., using the change in the specific dielectric constant [714, 879]. This technique, unlike the conventional method using a waveguide and horn antenna, features a coaxial cable and patch antenna that can be used at cryogenic temperatures, leading to the development of a slush hydrogen densimeter with a high accuracy of within  $\pm 0.5\%$ .

## 6.11 Storage of Gaseous Compressed Hydrogen

It is obvious that for large rocket engines, hydrogen will be used only in the form of liquid (or possibly slushed) hydrogen; however, for small thrusters, gaseous hydrogen has been evaluated as well, also in combination with electrolysis of water on board of satellites or crewed spacecraft. The compressed gaseous hydrogen will have to be stored between the point and time of manufacture and the point and time of use in a GOX/GH<sub>2</sub> rocket engine. Various methods for storage of gaseous hydrogen have been evaluated. Compressing the gas for storage is very energy intensive and may be prohibitively expensive in some locations with only limited electrical energy. Compressed gas cylinders are heavy and bulky, but at least they do not require permanent attention like a liquid hydrogen tank.

Storage of gaseous compressed hydrogen would also be useful for non-rocket applications of hydrogen such as for fuel cells or combustion engines in automobiles. Temporary storage of gaseous hydrogen boiloff from liquid hydrogen storage facilities instead of venting it would be one way to preserve a potential energy source for later use instead of wasting it in a flare stack.

### 6.11.1 Adsorption on Metal Hydrides

Hydrogen is the ideal, clean fuel for a variety of applications, but storability is difficult. Many methods have been evaluated for storage of hydrogen at room temperature instead of under cryogenic or supercritical conditions. Iron/titanium alloys will become saturated with hydrogen and form intermetallic hydrides, causing the metal particles to swell. This process is readily reversible. There have been entire conferences devoted to hydrogen storage and books have been written on hydrogen storage [880].

### 6.11.2 Hydrogen Storage in Intermetallic Metal Hydrides

Storage of hydrogen gas adsorbed on metal hydrides allows storage at lower pressures compared to the storage of the same amount of gas by simply compressing it in an empty tank that does not contain any absorbing metal hydride; however, the release

of hydrogen from the metal hydride is endothermic and requires additional heating. Metal hydrides have been evaluated for both mobile and stationary storage installations, but if they ever find any actual use, it would be more likely for stationary installations such as fuel cell batteries. Storage of hydrogen in metal hydride tanks as part of an electrolysis/fuel cell battery for load leveling of electric utilities has been evaluated. Metal hydrides are too heavy for hydrogen storage for rocket propulsion use. Reversible adsorption of hydrogen on metal hydrides can also be used for purification of hydrogen and isotope separation.

#### **6.11.3 Hydrogen Storage in Catalyzed Complex Covalent Metal Hydrides**

Hydrogen storage in catalyzed complex covalent metal hydrides undergoing reversible reactions is unlikely to be suitable for rocket propulsion [881].

#### **6.11.4 Hydrogen Storage by Adsorption on Nanotubes**

Storage of hydrogen by adsorption on carbon nanotubes would result in some weight savings compared to storage in iron-titanium hydrides, but it is most likely not suitable for rocket propulsion.

## **7 Safety and Hazard Properties of Hydrogen**

If hydrogen fuel cell cars become more widely accepted, hydrogen will most likely be transported from large, central hydrogen synthesis and liquefaction plants to distribution centers and refueling stations in the form of liquid hydrogen. The causes and consequences of potential accident scenarios in this distribution network have been reviewed [882]. Gas accumulation and explosion hazards were well studied, including experimental studies at full scale in refueling station geometries and unconfined explosions in congested regions; however, there was little information related to gas accumulation and explosions arising from a spill of LH<sub>2</sub> in a confined space. NASA has issued safety standards for the safe handling of liquid hydrogen [883–886].

### **7.1 Liquid Hydrogen Transportation Accident History**

This section is limited to accident histories involving moving vehicles carrying liquid hydrogen. Other accidents, occurring at stationary locations, will be reviewed in Section 9 below.

A web site <https://h2tools.org/lessons> offers a timely summary of lessons learned from accidents with hydrogen. Most of the accidents involved compressed gaseous hydrogen and only very few liquid hydrogen accidents were reported in that database.

The cause and lessons learned from accidents/incidents with hydrogen in NASA operations were reviewed [887]. The cause factors for the mishaps were reviewed and it was shown that although few accidents occurred, the number could have been further reduced if the established NASA rules and regulations had been strictly followed. The report included a compilation of 96 hydrogen mishaps, a description of the accidents and their causes.

## 7.2 Fire Hazards of Hydrogen

The following sections on ignition, combustion, explosion, and detonation of hydrogen in mixtures with air or oxygen are dealing with more academic studies, not directly relating to application of hydrogen in rocket engines. Many of these studies were motivated by applications of hydrogen as an energy storage medium other than in rocket propellants.

There is an international professional society exclusively devoted to the safety of hydrogen use [888]. The mission of the International Association for Hydrogen Safety, also called “HySafe,” is to facilitate the international coordination, development and dissemination of hydrogen safety knowledge by being the focal point for hydrogen safety research, education and training. Table 49 is a comparison of physical and safety properties of hydrogen with those of methane and gasoline.

There are numerous studies of the hazards associated with the production and handling of liquid hydrogen, and the repeated message is that ignition sources must be avoided anywhere near where hydrogen is stored and transferred [889, 890]. A quantity-distance table for the storage of liquid hydrogen was developed. The vaporization of liquid hydrogen from a surface was treated as a problem in heat transfer theory. Two extreme cases were considered: **(1)** the transfer of heat occurs at constant temperature drop between the boiling liquid and the hot surface, and **(2)** the transfer of heat is limited by the rate at which it can flow to the surface from a hot insulating medium. The available data indicated that the former case **(1)** is applicable when vaporizing from a conducting surface and, initially, when vaporizing from an insulating medium; the latter case **(2)** is applicable after initial flash vaporization has occurred from the insulating medium. The vaporization rate determines in part the rate at which flammable hydrogen vapor-air mixtures are formed above a spill area; however, the rates at which heat is transferred to the vapor, and air is brought in contact with it also are of importance. The distribution of flammable mixtures above a spill area was determined experimentally. In general, flammable mixtures were found to be both above and within the visible vapor cloud.

Federal regulations applicable to the manufacture and maintenance of hydrogen equipment and to the distribution of gaseous and liquid hydrogen in the United States were summarized and presented in a table of regulatory references [891]. A similar

**Table 49:** Safety properties of hydrogen in comparison to methane and gasoline.

| Property                                          | Units                               | Hydrogen     | Methane      | Gasoline   |
|---------------------------------------------------|-------------------------------------|--------------|--------------|------------|
| Triple-point pressure                             | atm                                 | 0.0695       | 0.1159       | —          |

table of references was presented for non-mandatory standards and guidelines pertinent to hydrogen safety and hydrogen facilities/equipment specifications. These two tables summarized information that had been published in industry, universities and government agencies for the safe production, storage, and handling of hydrogen.

NASA has developed a Hydrogen Systems Safety Standard, which establishes a uniform process for hydrogen system design, materials selection, operation, storage, and transportation of hydrogen [305]. This is an expanded version of the NASA Hydrogen Safety Handbook originally prepared by P.M. Ordin. The guidelines include suggestions for safely storing, handling, and using hydrogen in gaseous (GH<sub>2</sub>), liquid (LH<sub>2</sub>), or slush (SLH<sub>2</sub>) form, whether used as a propellant or non-propellant. The safety standard handbook contains 9 chapters detailing properties and hazards, facility design, design of components, materials compatibility, detection, and transportation. The appendices include assessment examples, scaling

laws, explosions, blast effects and fragmentation, codes, standards, NASA directives, design of pressure relief devices along with a list of tables and figures, abbreviations, a glossary, and an index for ease of use. There is also a companion document, Safety Standard for Oxygen and Oxygen Systems (NSS1740.151996). See also [892].

While initially prompted by the use of liquid hydrogen as a rocket propellant, the experience gained will in the future benefit the average consumer through the planned use of hydrogen as automotive (mostly compressed hydrogen, not liquid hydrogen) fuel and possibly even airplane fuel.

### 7.3 Liquid Hydrogen Spill Hazards

If liquid hydrogen is accidentally spilled, all potential sources of ignition must be removed and the spill site should be evacuated. One can then observe from a safe distance until all hydrogen is evaporated and it has warmed sufficiently that it will rise in air like a balloon [890, 893].

One unit volume of LH<sub>2</sub> converts to 845 times its volume of gas (at room temperature) as it evaporates and 1 kg of LH<sub>2</sub> creates a cloud of 11.1 m<sup>3</sup> of GH<sub>2</sub> at room temperature.

If a liquid hydrogen leak or spill occurs, a cold hydrogen cloud could flow horizontally for some distance or even downward, depending on the terrain and weather conditions. Cold hydrogen will travel some distance before it has warmed enough that it becomes buoyant in air.

Various investigations of the occurrence of detonations in the case of spillage and evaporation of liquid hydrogen have been carried out but they did not yield an unambiguous answer to the question what conditions lead to detonable mixtures in air. There have been studies of the laws governing the formation and floating buoyancy of a cloud of air/hydrogen mixtures when there are instantaneous emissions of small quantities of gaseous hydrogen, trying to calculate the TNT equivalent of such explosions, and the laws of combustion when evaporation takes place and the jet escape of hydrogen under pressure from pipe systems. There have been estimates of the coefficients of turbulent diffusion and of the velocities of uplift of air/hydrogen mixtures and the mass of hydrogen capable of taking part in the detonation when there is an instantaneous spillage and evaporation of liquid hydrogen. Only few measurements of the concentration and temperatures for the case of prolonged evaporation of hydrogen from spilled pools had been made until 1981. The distribution of hydrogen concentrations was calculated in an axisymmetric stationary regime of evaporation of liquid hydrogen including the convective uplift of turbulent vortices in free space [894].

The evaporation rates of liquid hydrogen spilled onto the ground were measured in laboratory tests [895]. To simulate the ground where the spill occurred, samples of concrete, dry sand, and wet sand layers were placed into a see-through vacuum-insulated cylindrical glass vessel. Based on the temperature variations within the layer and

detailed observation through the side of the vessel, the heat transfer modes controlling the evaporation phenomenon were visualized. When a wet sand layer was used, the liquid hydrogen did not soak into the layer, because the frozen layer of water between the liquid and the sand layer acted as a barrier. When a concrete layer was used, the liquid vaporized above the layer. In these cases, the evaporation rates were inversely proportional to the square root of the time, except in the early stage just after the start of vaporization. This relationship could be predicted by a simple calculation of heat conduction within the layer. When a dry sand layer was used, liquid hydrogen did not soak into the dry sand layer, and the evaporation mechanism seemed to be the same as that for the wet sand layer, because the air contained within interparticle cavities in the dry sand layer solidified at the boiling point of liquid hydrogen and clogged the pores.

The most important issues to be resolved in the safety assessment of accidental massive LH2 spills are the position, the size, and the hydrogen concentration of the vapor clouds formed after the spills. The multi-phase hydrodynamics analysis code (CHAMPAGNE) was used to calculate the behavior of hydrogen during the experiment in which 5100-L quasi-instantaneous LH2 spills were performed at the NASA White Sands Test Station [896].

In a study of worst-case accident scenarios with liquid hydrogen tanks, explosions of 125-L liquid hydrogen tanks with different fill pressures and fill levels were cut open by a linear shaped charge, which immediately ignited the released liquid and gas [897]. The fireball spread to 75% of its maximum size within 0.2 s. After 1–2 s the fireball began to separate from the ground level and rose to 10–20 m within another 1–2 s. The whole event lasted 3–4 s. The radiation emitted from the fire was measured.

A 3-D time dependent finite volume code was used to model liquid hydrogen release experiments [898]. The experiments were performed by Batelle Ingenieurtechnik for the Federal Institute for Materials Research and Testing (Bundesanstalt für Materialforschung und Prüfung, BAM), Berlin and they mainly deal with LH2 near ground releases between buildings. The simulations illustrated the complex behavior of LH2 dispersion in the presence of buildings, characterized by complicated wind patterns, plume back flow near the source, dense gas behavior at near range and significant buoyant behavior at the far range. The simulations showed the strong effect of ground heating in the LH2 dispersion. The model also revealed major features of the dispersion that had to do with the “dense” behavior of the cold hydrogen and the buoyant behavior of the “warming-up” gas as well as the interaction of the building and the release wake. Such a predicted behavior was in qualitative and even quantitative agreement with the experiment.

In earlier work a 3D time-dependent fully compressible CFD code was applied against large-scale LH2 release experiments in the vicinity of buildings. Subsequently the code was applied to simulate large-scale LH2 spill tests in open, unobstructed environments [899]. A series of simulations were performed to investigate the effects of the source model (jet or pool), the modeling of the earthen sides of the pond around

the source and the inclusion of a contact ground heat transfer. The predicted hydrogen concentrations (% by vol.) were compared against the experimental data at the available sensor locations. In addition, the predicted structure of the concentration field was compared against the experimental, which was originally derived from temperature measurements. Modeling the source as a two-phase jet pointing downwards, including the modeling of the earthen sides of the pond as a fence and the contact heat transfer to the ground gave the best agreement with respect to experimental behavior.

The understanding of cryogenic pool spreading and its vaporization is require to analyze an accident sequence with an inadvertent spillage of LH<sub>2</sub>, e.g., after failure of a transport container tank or the rupture of a pipeline [900]. This stage of an accident scenario is the source term for the subsequent analysis steps of atmospheric dispersion and, in the presence of an ignition source, the combustion of the hydrogen-air vapor cloud. A computer model has been developed which was able to simulate the spreading and vaporization of a cryogenic liquid under various conditions such as different grounds (solid, water). It was based on the so-called shallow-layer differential equations taking into account physical phenomena, such as ice formation if the cryogen is spilled on a water surface. One can compare an LH<sub>2</sub> spillage to the corresponding release of other cryogens, such as liquid natural gas or liquid oxygen.

Experiments were made to investigate spills of liquid hydrogen at a rate of 60 L/min. Measurements made on both unignited and ignited releases included concentration of hydrogen in air, thermal gradient in the concrete substrate, liquid pool formation, and temperatures within the pool, flame velocity within the cloud, thermal radiation, IR and visible spectrum video records and sound pressure measurements [901]. The tests which impinged hydrogen onto the ground all produced a pool of liquid once the ground had cooled sufficiently, usually about 2 minutes into the release. In addition, a large solid deposit, which had the appearance of “snow,” was produced. Both the liquid and the “snow” persisted for several minutes after the release ended. The thermocouple measurements showed a step near 77 K in the temperature traces as the temperature increased after the LH<sub>2</sub> release had ended. This was indicative of the melting and boiling of the condensed air. The release of liquid hydrogen at a rate consistent with the failure of a 1-in. transfer line produced a flammable mixture at least 9 m downwind of the release point.

The hazards arising from an accidental release of hydrogen from cryogenic liquid storage or compressed gas storage tanks and the subsequent damage consequences were compared, including hydrogen cold cloud, fire ball, jet fire, flash fire, and vapor cloud explosions [902]. The severity of cold effect, thermal effects, and explosion overpressures were evaluated using certain damage criteria. Results showed that for instantaneous releases of liquid hydrogen, the sequence of damage effect distances is: vapor cloud explosion>flash fire>cold cloud> fireball. For continuous releases of liquid hydrogen, the order of damage effect distances is: vapor cloud explosion>jet fire>flash fire>cold cloud. The vapor cloud explosion is the leading consequence of both instantaneous and continuous releases and may be used for the determination

of safety distances of a liquid hydrogen tank. The damage effect distances of liquid hydrogen tanks were compared with those of compressed hydrogen storages with equivalent mass. Results showed that the liquid hydrogen storage may be safer than 70 MPa gaseous storage in case of leak scenario but may be more dangerous than 70 MPa storage in case of a catastrophic rupture.

Several CFD models for predicting the movement of liquid releases, both two-phase flashing jets and pool spills, have been developed [903, 904]. The release of liquid hydrogen in the atmosphere may induce partial condensation or even freezing of the oxygen and nitrogen present in the air. In computations of two-phase jets it was assumed that the dispersed and continuous phases are in thermodynamic and kinematic equilibrium. A pool model was used to compute the spreading and vaporization of liquid hydrogen depositing on the ground and also the partial condensation or freezing of oxygen and nitrogen was taken into account. Simulations with these models were compared against selected experiments.

The different boiling regimes film boiling, transition boiling, and nucleation boiling after a release of liquid hydrogen into a pool were modeled by means of a code for wall heat transfer evaporation, which was implemented in a commercial CFD code and validated against LH2 spill experimental data [905].

A review of the data and detailed modeling of cryogenic releases in the scientific literature showed a dearth of validated models, or appropriate data to validate these models [906]. Challenges associated with modeling cryogenic hydrogen releases stem from the multi-phase flows and phase change behaviors encountered during these releases. In a reduced-order model that breaks stream-wise flow regimes for cryogenic releases into discrete zones, zones furthest from the release are expected to perform well where the jet has warmed to temperatures more characteristic of gaseous releases; however, in the zones near the release, complex thermodynamic state modeling and multi-phase flows require assumed models for relevant behavior, that had not yet been properly validated. A cryogenic hydrogen integral jet and plume model, COLDPLUME, has been updated for choked flows for cryogenic fluids.

A 3D model has been built for the simulation of liquid hydrogen spills on the ground, where the source of LH2 was modeled as a jet and placed near the ground [907]. The model was validated by the experimental results from the large-scale test of LH2 spill carried out by NASA in New Mexico in 1981, and then used to analyze the vaporization time of LH2 and the spreading range of gaseous hydrogen. The variation of hydrogen concentration distribution at different time nodes and different environmental conditions was presented as a function of wind velocity, wind temperature, and ground temperature. The flammable vapor cloud was found to undergo three different evolution stages, namely the initial stage, the quasi-steady spread stage, and the disappearance stage [908]. The composition differences between the cloud and undisturbed air play a major role in vertical turbulent fluctuation, while the wind will dominate with the increment of height in streamwise direction.

A 3D CFD model for large-scale liquid hydrogen spills was developed and validated by comparing it to the experiments carried out by NASA [909]. The effect of humidity on the development of hydrogen vapor cloud was quantified with the modified expressions of a model accounting for the phase changes of water and hydrogen. The results showed that the numerical prediction is more consistent with the experiment considering the presence of air humidity. The condensation of water in the atmosphere increases the buoyancy of the vapor cloud and promotes the diffusion of the cloud in a vertical direction. The dimension of the cloud in a streamwise direction changes little under conditions of different humidities due to the balance between the height-dependent wind speed and the induced buoyancy. The scope of visible cloud indicated by the condensed water vapor expands with the increasing air humidity, and still lies within the flammable domain when the relative humidity is approaching 75%.

#### 7.4 High Pressure Liquid Hydrogen Leak Jet Release Hazards

A model for computing hydrogen dilution distances for cold hydrogen releases was presented for leaks of room temperature gas and 80K high-pressure hydrogen gas [910]. The model accounted for a series of transitions that occurs from a stagnate location in the tank to a point in the leak jet where the concentration of hydrogen in air at the jet centerline has dropped to 4% by volume. The leaking hydrogen is assumed to be a simple compressible substance with thermodynamic equilibrium between hydrogen vapor, hydrogen liquid and air. It is assumed that further downstream the jet develops into an atmospheric gas jet where the thermodynamics are described as a mixture of ideal gases (hydrogen-air mixture). Simulations were presented for dilution distances in underexpanded high-pressure leaks from the saturated vapor and saturated liquid portions of a liquid hydrogen storage tank at 10.34 bar gauge (150 psig).

Venting of liquid hydrogen from lower stage propulsion systems can lead to two-phase flows, evaporation of the fuel and condensation of air [911, 912]. In a study of the non-equilibrium behavior associated with the injection of two-phase hydrogen jets into air, the air was treated as a binary mixture that condenses in equilibrium. The condensed hydrogen, however, was assumed to form a dilute suspension of spherical particles that evaporate at a finite rate. This partial equilibrium process was considered to take place under constant pressure in a one-dimensional inviscid stream tube configuration.

The hazard of cryogenic and combustible liquid rocket fuels (hydrogen and methane) leakage caused by spontaneous damage to tanks or rupture of pipelines is a potential problem for both applications. Numerical simulations have been performed to predict the differences in leakage and dispersion rates of the two fuels [913]. Based on liquid hydrogen release tests, a mixture four-phase flow model

considering the liquid hydrogen and air phase transitions has been developed. The liquid phase movements in the near field, combustible clouds and cold effect clouds movement in the far field were investigated. The Froude number is a dimensionless number defined as the ratio of the flow inertia to the external gravity field. With Froude number increases from 0.47 to 3.72, liquid hydrogen represents a downward trend while liquid methane shows a downwind trend. For combustible clouds, the movements of hydrogen are larger than those of methane in both downwind and vertical direction on a quasi-stable state. For cold effect clouds, the dispersion of methane is greater than that of hydrogen in Froude numbers of 0.47, 0.93, or 1.86, but then smaller in a larger Froude number of 3.72.

## 7.5 Hydrogen Plume Dispersion in the Atmosphere

Hydrogen spill and vapor cloud dispersion experiments were performed by NASA to obtain basic information regarding the physical phenomena governing the dispersion of flammable clouds formed as the result of spills of large quantities of liquid hydrogen [914, 915]. The experiments consisted of ground spills of up to 5.7 m<sup>3</sup> (1500 gallon) of liquid hydrogen, with spill durations of approx. 35 s. Instrumented towers, located downwind of the spill site, gathered data on the temperature, hydrogen concentration and turbulence levels as the hydrogen vapor cloud drifted downwind. Visual phenomena were recorded by motion picture and still cameras. Preliminary results of the experiments indicated that, for rapid spills, thermal and momentum-induced turbulences cause the cloud to disperse to safe concentration levels and become positively buoyant long before mixing due to normal atmospheric turbulence becomes a major factor. An adiabatic mixing model has been developed to deduce hydrogen-air mixture ratios for temperature measurements obtained within the cloud formed by liquid hydrogen spills. The model should be a useful tool for describing the hydrogen concentrations within the plume.

A large-scale experiment was set up to study the mechanisms of the formation of an unconfined gas cloud resulting from liquid hydrogen spillage and the associated mixing process and turbulence effects [916]. Dispersion tests were performed with cryogenic helium instead of hydrogen, presenting dispersion characteristics similar to liquid hydrogen (buoyancy). Flow rates up to 3 kg/s have been investigated and the instrumentation allowed the observation and quantification of buoyancy effects including internal turbulence. Those results constitute an original set of data which can be used as a basis for the development of dispersion software and reinterpretation of other existing databases resulting from LH2 spill tests.

Experiments and simulations were performed to evaluate the potential hazards of a liquid hydrogen spill accident [917, 918]. A CFD code was used to simulate the liquefied hydrogen spill experiments conducted. In these tests, LH2 was spilled at a fixed rate of 60 L/min. in several directions and for several durations. Factors that influ-

enced the vapor dispersion under cryogenic release conditions were: the air humidity, the wind direction, and the slip effect of droplets formed by both the cryogenic liquid and the condensation of air humidity. Two horizontal releases, one along the ground and the other one at a distance above the ground, and one vertical release were examined with spill rates of 60 L/min. The presence of humidity in the atmosphere has a distinct effect on the vapor dispersion. When humidity is present and it is cooled, it condenses and freezes due to the low prevailing temperature ( $\sim 20$  K near the release), and releases heat. In addition, during the release hydrogen droplets are formed due to mechanical and flashing break-up, and water droplets and ice crystals are formed due to humidity condensation. Two models were tested: a hydrodynamic equilibrium model, which assumed that the phases are in thermodynamic and kinematic equilibrium and the non-hydrodynamic equilibrium model (slip model), which assumed that the phases are in thermodynamic equilibrium but they can obtain different velocities. The computational results were compared with experimental measurements, and it was concluded that humidity along with the slip effect influences the buoyancy of the cloud to a great extent. The effect of each variable on the rate and shape of vapor cloud dispersion was examined.

A non-homogeneous equilibrium model (NHEM) was used to model flammable cloud dispersions following liquid hydrogen spills under various weather conditions and validated by a large scale LH2 spill experiment [919]. The predicted data were in good agreement with the experiment. Three primary questions of the hydrogen dispersion process were addressed: the maximum spreading range, the minimum distance above the ground, and the duration time of the flammable cloud in the atmosphere. Three major influence factors were selected to simulate various weather conditions, including ambient temperature (coupled with ground temperature), wind speed, and atmospheric pressure. The hydrogen dispersion can be increased with increased wind speed and be impeded by increased atmospheric pressure. The hydrogen dispersion process in four seasons of a year appears to follow a different trend.

The flashed vapor fraction at the pipe exit of liquid hydrogen leaking into air at sea-level pressure was estimated assuming isenthalpic expansion combined with the NIST equation of state [920]. Modeling the condensation of ambient air humidity and air components and imposing transient wind profile were part of a homogeneous equilibrium model (HEM) and then compared to the NHEM to account for slip effects of the non-vapor phase. A comparison of the momentum slip model with the algebraic slip model showed that the latter overestimated the slip velocity for large particles and thus it should be used only with precaution.

One study revealed that humidity can reduce the longitudinal distance of the zone within the lower flammability limit (LFL) [921]. Simulations with liquid methane release have been performed and compared to the liquid hydrogen simulations in order to identify the differences in the behavior of the two fuels as far as the humidity effect is concerned. It was shown that in methane spills the buoyancy effect in presence of humidity is smaller than in hydrogen spills and it can be considered almost negligible.

The dilution of hydrogen vapor clouds formed by liquid hydrogen spills under different conditions of spill amount, spill rate, and liquid mass fraction were numerically investigated by three-dimensional CFD simulations [922]. Time variation of the moment of maximum hydrogen concentration was most sensitive to the liquid mass fraction, followed by the spill rate, and finally the spill amount. The dilution process was nearly unaffected by the spill amount. With the increment of spill rates, the dilution speed first decreased and then remained approximately unchanged, which can be attributed to the combined effects of the gaseous hydrogen generated per unit time and the source disturbances generated by the spill and evaporation process. The turbulence induced by the evaporation of liquid hydrogen promotes the mixing and dilution processes, while the temperature drop in the ground and the ambient air due to liquid evaporation has little influence on the overall dilution of the vapor cloud.

Venting of hydrogen to depressurize the receiving storage tanks is a routine part of the LH2 delivery and transfer process. The behavior of cold hydrogen plumes has not been well characterized because of the sparsity of empirical field data, which can lead to overly conservative safety requirements from the government regulators [923]. A prototype hydrogen analyzer was field deployed during an actual LH2 venting process and the data were used to characterize the hydrogen plume formed during LH2 storage tank venting. Hydrogen above the LFL was detected as much as 2 m lower than the release point, which is not predicted by any of the existing models. Some hydrogen was detected at ground level, although only at levels below the LFL.

## 7.6 Open Air Buoyancy of Hydrogen Flames

Hydrogen gas by itself and in the absence of flames will rise in air as soon as it is warm enough. If a bubble of hydrogen gas is ignited, the updraft caused by hot gases will accelerate the upward transposition of the hydrogen cloud and the surrounding flame. The average burning rate and expansion of burning hydrogen clouds was studied by rupturing hydrogen-filled balloons and igniting the released cloud of gas [924]. The maximum burning rate of the cloud was 2.5 m/s and occurred near stoichiometric dilution near the cloud center. The maximum flame propagation rate (19 m/s) occurred at higher hydrogen concentrations.

## 7.7 Pool Burning of Liquid Hydrogen Spills

In controlled spill and pool burning experiments with liquid hydrogen in containers with different diameters it has been noted that liquid hydrogen pools burn much faster than any other spilled rocket propellant or commercially used fuel (Figures 64 and 65) [889, 925, 926].

**Figure 64:** Dependence of pool burning rate on pool diameter. (Reproduced and modified from [889].)

When conducting this type of experiment, one must make sure that the spilled liquid is ignited before air has a chance to condense on top of it and form explosive mixtures. The effect of air condensation on pool burning is described at the end of this section.

Pool burning tests with spilled liquid hydrogen and immediate ignition led to the following conclusions [497, 499, 927]:

1. Unconfined mixtures of air and hydrogen will not explode, but burn quietly if the ignition is by a spark or a flame.
2. The heat radiation of an air/hydrogen flame is only 1/10 of the radiation intensity of a hydrocarbon flame. Firefighting crews can operate closer to a hydrogen fire without getting scorched by heat radiation. A hydrogen fire does not expand as rapidly to adjacent combustible structures as a hydrocarbon fire. A pool of burning liquid hydrogen is consumed in 1/10 of the time of a pool of gasoline or kerosene of the same volume.

**Figure 65:** Regression of liquid surface of liquid hydrogen burning in metal Dewars of different diameters. (Reproduced and modified from [889].)

The emissivity of a hydrogen flame is only 0.09 compared to the emissivity of a black body radiator which is close to 1.0. Hydrogen escaping from a pipe or at the top of a flare stack gives a cleaner, nearly invisible flame than liquid hydrogen spilled on the ground and burning with entrained contaminants. Radiation measurements showed that persons could approach a large hydrogen fire for 30 s to as close as 54 m without suffering heat burns [497, 499]. For kerosene JP-4 the safety distance would have to be 205 m, 4 times as much as for hydrogen. Tests with liquid hydrogen poured into a pan and delayed ignition showed that initially air does not condense into liquid hydrogen because the boiling liquid is surrounded by a cushion of cold hydrogen gas. Atmospheric moisture absorbs thermal energy radiated from a hydrogen fire and can reduce the radiation values recorded from laboratory experiments in dry air.

In order to measure the hydrogen spill hazards, 4.7 L of liquid hydrogen was poured into a concrete-lined basin and ignited after different delay times. In each case the gas above the pool and then the liquid burned without detonation. Pressure gauges showed some pressure build-up in deep pools that were surrounded by four walls. The pressure was higher than with a pool on flat ground. It was recommended to place hydrogen storage facilities on flat terrain without confining walls to avoid overpressure during combustion. The regression rate due to evaporation (not burning) of liquid hydrogen is initially 13–18 cm/min. After about 3 min. and after the walls of the pool have cooled down, the regression rate is only 4 cm/min. If liquid

hydrogen is poured onto porous ground or onto a bed with river pebbles instead of into a concrete-lined basin, it evaporates much faster.

In a series of LH2 spill tests, spills were first investigated experimentally as large-scale unignited spills of LH2 at a rate of 60 L/min by measuring the concentration of hydrogen in air, thermal gradients in a concrete substrate, liquid pool formation and temperatures within the pool [928]. Later, three different conditions of jet-fires in high and low wind conditions, “burn-back” of ignited clouds and secondary explosions after “burn-back” representing a realistic ignited spill of LH2 were tested and flammability limits of an LH2 vapor cloud, flame speeds through an LH2 vapor cloud and radiative heat levels after ignition were measured [929]. An attempt was made to estimate the overpressure of an explosion that occurred during one of the LH2 releases.

## 7.8 Firefighting of Liquid Hydrogen Fires

It is extremely difficult to extinguish liquid hydrogen fires. The first step should be to interrupt the source of hydrogen if it is a local leak.

Carbon dioxide fire extinguishers can knock down hydrogen fires only if the carbon dioxide is applied very rapidly so that it cuts off the supply of air. When feeding CO<sub>2</sub> into an air/hydrogen fire there is the potential that some of the CO<sub>2</sub> will be reduced to CO which then constitutes an inhalation toxicity hazard.

Applying water to a hydrogen fire has very little effect. Water is only useful to cool the surrounding area and prevent the spread of the fire. The hydrogen flame itself cannot be extinguished by water spray. It has been recommended to use a combination of nitrogen-filled aqueous foam and bicarbonate-filled dry powder fire extinguishers to fight hydrogen fires [930, 931]. Many chemicals have been evaluated as potential inhibitors for air/hydrogen explosions. One of the chemicals tested was iron pentacarbonyl but this compound is extremely toxic and will never be used. Confined liquid hydrogen combustion was effectively suppressed by air-halogenated hydrocarbon mixtures with 13–65% of inhibitor.

Fighting hydrogen fires is made difficult by the fact that hydrogen flames are not very luminous and are hard to see during daytime (see section “Radiation from Hydrogen Flames”). It has been recommended to equip firefighting crews with night vision goggles in which the infrared emission of hydrogen flames is better visible [932].

## 7.9 Ignition Hazards in the Vicinity of Hydrogen Facilities

As the Hindenburg dirigible disaster and other industrial accidents have shown, hydrogen in air has a very low ignition energy threshold and is quite susceptible to ignition by electrostatic discharges. For this reason, electrostatic accumulation of electric charges in the vicinity of hydrogen operations in air must be avoided. Electrostatic dis-

charges, even small ones like you encounter when bending down to the water drinking fountain after walking on synthetic fiber carpet, are sufficient to ignite a hydrogen fire or even a hydrogen explosion. Electrostatic charges may also accumulate when liquid hydrogen flows through pipes or if gaseous hydrogen is vented to the air [326].

Because of the very low electrical conductivity of hydrogen electrostatic charges in liquid hydrogen in an electrically insulated tank last a thousand times longer than in kerosene, but they do not reach as high values because the breakthrough voltage in hydrogen is lower than in kerosene: Hydrogen 10 V/cm; kerosene JP-4 800 V/cm. Electrostatic charges develop in particular during two-phase flow of liquid hydrogen through a line. This has also been observed with other cryogenic liquids.

In order to prevent the build-up of electrostatic charges and the potential for accidental ignition, all ground service equipment for liquid and gaseous hydrogen should be grounded in accordance with NFPA regulations.

### **7.9.1 Accidental Ignition Hazards**

Most people handling hydrogen and other flammable gases are fully aware of the ignition hazard due to electrostatic discharges. Only few people are aware of the potential of self-ignition if high-pressure hydrogen gas escapes into air.

Pressurized hydrogen released into the air can undergo spontaneous ignition [933]. Previous research had been limited to conduct tests at the pressure conditions below about 200 bar due to the experimental difficulties and danger. Experimental studies were now conducted to observe the spontaneous ignition of hydrogen released at pressures above 200 bar. The ignition and flame were detected using a photodiode inside the tube and a high-speed camera outside the tube. The spontaneous ignition limits were established with various internal tube diameters and lengths of the tube at the high-pressure conditions.

### **7.9.2 Electrostatic Discharge Sensitivity of Hydrogen**

The minimum spark energy required for ignition of hydrogen in air is about an order of magnitude less than that for methane or gasoline. A discharge of static electricity from a human body may be sufficient to ignite any of these fuels in air. Sparks with 10 mJ energy may be produced in such electrostatic discharges from well-insulated bodies walking on carpets or coming into contact with moving machinery. The minimum ignition energy of hydrogen in air is 0.017 mJ, compared to 0.274 mJ for methane in air.

Because of the very low ignition energy requirements and wide range of flammability for mixtures of hydrogen and air (or oxygen), extreme care must be taken to remove all possible ignition sources from hydrogen facilities. Special concern is about the potential charge build-up in storage tank and transfer equipment during the flow of liquid hydrogen and charge build-up during venting of boil-off gases from missile and storage tanks [326]. The friction of high-pressure hydrogen gas exiting (venting)

into air can build up sufficient static charges to ignite the jet of gas. This mechanism of accidental ignition is reviewed in Section 7.9.2.3 “Spontaneous Ignition of High-pressure Hydrogen Gas Leaks.”

### 7.9.2.1 Minimum Ignition Energy of Air/Hydrogen Mixtures

The minimum ignition energies for hydrogen in air and in mixtures of 21 vol.-% oxygen, 79 vol.-% diluent (other than nitrogen) at 101 kPa (14.7 psia) are shown in Figure 66 from [934]. The lowest ignition energies occur for stoichiometric concentrations of hydrogen (29 Vol.-% in these mixtures). The ignition energies in Figure 66 are lowest for diluents with small heat capacities and low thermal conductivities, and highest for helium, which has a relatively high thermal conductivity. The minimum ignition energy for hydrogen in oxygen is significantly lower than for hydrogen in air. The lowest value found in the literature is  $1.2\mu\text{J}$  [935]; the lowest value for hydrogen in air is  $19\mu\text{J}$ .

**Figure 66:** Minimum ignition energies for hydrogen in air and in mixtures of 21 vol.-% oxygen, 79 vol.-% diluent gas. (Reproduced and modified from [934].)

Figure 67 shows the effect of pressure on the minimum ignition energy of hydrogen in air. The minimum required ignition energy increased with decreasing pressure. Plotting the logarithm of the minimum required ignition energy versus the logarithm of the pressure gives a near-linear relationship, Figure 68. See also [936].

**Figure 67:** Effects of pressure on the minimum required ignition energy for hydrogen in air. (Reproduced and modified from [934].)

**Figure 68:** Effect of reduced pressure on the minimum required ignition energy for stoichiometric air/hydrogen mixtures. (Reproduced and modified from [934].)

### 7.9.2.2 Autoignition of Hydrogen in Air

Although hydrogen has a higher autoignition temperature than methane or gasoline, its low ignition energy makes it more readily accidentally ignitable than either of the hydrocarbon fuels. Ignition can occur on hot surfaces or by contact with hot air. These ignitions occur with a certain delay, unlike spontaneous ignition observed with high pressure hydrogen gas leaks.

The autoignition of hydrogen in air should be determined in accordance with ASTM E659, but many reports in the literature used different methods, resulting in a wide scatter of reported autoignition temperatures. It is assumed that those reports are for stoichiometric air/hydrogen mixtures which are most likely to ignite. The hot surface that is brought into contact with air/hydrogen as part of this test must be chemically inert and non-catalytic.

Other sources listed the autoignition temperature of hydrogen on inert surfaces in air as 793 K (520 °C), compared to 903 K (630 °C) for methane. A temperature of 858 K (585 °C) was reported as autoignition temperature of hydrogen in air in [521]. The Praxair MSDS for hydrogen gives an autoignition temperature of 839 K (566 °C).

One hydrogen safety manual gave the range of reported autoignition temperatures for stoichiometric hydrogen in air at 101.3 kPa (14.7 psia) as 773–850 K (932–1070 °F). For comparison, in stoichiometric mixtures with oxygen, the autoignition temperature is 773–833 K (932–1039 °F).

### 7.9.2.3 Spontaneous Ignition of High-pressure Hydrogen Gas Leaks

Accidental spontaneous ignition or self-ignition or autoignition of high-pressure hydrogen gas leaking into surrounding air has been observed on several occasions. Autoignition of flowing hydrogen was reported as early as 1918. Hydrogen flowing through an aspirator in the presence of air would occasionally autoignite. It was observed that an electric charge built up when the hydrogen/air mixture passed over a wire which was placed perpendicular to the direction of flow, but electrically insulated from the aspirator. Sparks 7 in. long were observed jumping to the aspirator. Various phenomena such as friction-induced ionization or electrostatic charge accumulation, test section surface irregularities, boundary layer effects, acoustic resonance, thermodynamic non-equilibrium, and diaphragm rupture have been considered as the cause of low-temperature ignition. While most of these phenomena can cause low-temperature ignition, it is not known which one of them or which combination of them is actually responsible for the low-temperature ignitions [937]. The resulting fire of the high-velocity stream of hydrogen has been described as “jet fire.”

During a compressed hydrogen gas high-pressure venting experiment conducted to make acoustic measurements the vented hydrogen autoignited and an explosion ensued that caused substantial building damage [938, 939]. At the moment of ignition, the hydrogen cloud was about 30 feet wide and 150 feet high.

While self-ignition of hydrogen is undesirable for accidental high-pressure gas releases, self-ignition of supersonic air/hydrogen mixtures is desirable in scram-jets [940]. A correlation of self-ignition data for supersonic air/hydrogen mixtures in configurations representative of scramjet combustors examined injection from transverse fuel jets on walls, transverse jets behind swept and unswept steps, and transverse injection ahead of swept and unswept steps and strut bases. The results provided useful guidance for predicting self-ignition in a variety of applications. The likely regions for self-ignition in a combustor were identified. See also [941].

Hydrogen releases from a high-pressure chamber were modeled to investigate the real gas effects at high pressures [942]. In the first method, an analytical model was developed to simulate time histories of stagnation properties of hydrogen inside the chamber as well as sonic properties of hydrogen at the orifice. Thermodynamic relations describing the specific heat, internal energy and velocity of sound were derived based on Beattie-Bridgeman state equation. In the second approach, a 3-D unstructured tetrahedral finite volume Euler solver was applied to numerically simulate the hydrogen release.

A large-scale hydrogen jet experiment was performed in which 27 kg of hydrogen was released vertically into the open atmosphere in a period of about 30 s to simulate the bursting of interconnecting piping between large high-pressure storage tanks [943]. The hydrogen plume spontaneously ignited early in the release.

The various autoignition mechanisms have been investigated, but the resulting conclusions arrived at by various investigators do not always match [944, 945]. Mechanisms which have been proposed in the past are the reverse Joule-Thomson effect, electrostatic charge generation, diffusion ignition, sudden adiabatic compression and hot surface ignition. Of these, some have been characterized by means of computer simulation rather than by experiment, and hence are not validated. There are discrepancies between the theories, releases known to have ignited, and releases which are known to have not ignited [946, 947]. Compression ignition, Joule-Thomson expansion, diffusion ignition, and hot surface ignition are unlikely ignition mechanisms for most accidental releases of hydrogen at ambient temperature. It is possible that some form of electrostatic charging is a part of the mechanism where spontaneous ignition of leaks of hydrogen from high pressure has occurred at ambient temperature. There is the possibility that when hydrogen does ignite on release, two or more of the postulated mechanisms are responsible together [948, 949].

An appreciable difference between the calculated and measured values of delay of self-ignition upon injection of pre-mixed air/hydrogen mixture into a preheated volume was revealed in the experiments of Ciccarelli et al. who studied the effect of initial temperature on the initiation of gas detonation [950, 951]. It was noted that conventional calculations by standard kinetic schemes predicted delay times much longer than those measured.

A numerical and experimental investigation of hydrogen self-ignition as a result of the formation of a primary shock wave in front of a cold expanding hydrogen gas

jet showed that temperature increase, as a result of this shock wave, leads to the ignition of the air/hydrogen mixture formed on the contact surface [952, 953]. The required condition for hydrogen self-ignition is to maintain the high temperature in the area for a time long enough for hydrogen and air to mix and inflammation to take place. Calculations of the self-ignition of a hydrogen jet were based on a physicochemical model involving the gas-dynamic transport of a viscous gas, the kinetics of hydrogen oxidation, the multi-component diffusion, and heat exchange. It was found that the reservoir pressure range, when a shock wave formed in the air during depressurization, has sufficient intensity to produce self-ignition of the air/hydrogen mixture formed at the front of a jet of compressed hydrogen.

Self-ignition of air/hydrogen gas mixtures was measured behind reflected explosive pressure waves at moderate (below 1200 K) temperatures and elevated pressures [954]. The experiments were performed in a modified shock tube which provided generation of explosive pressure waves. The explosive waves were characterized by a jump of parameters of shock-compressed gas (pressure, temperature) at the front with their subsequent continuous decrease. This explains hypothetical pre-explosion preheating of combustible mixtures by compression waves. The experiments involving standard shock waves (with constant pressure/temperature levels) revealed a significant deviation (by a factor of 10 and more) of measured values of the delay of self-ignition from the calculated values.

Releases of  $\text{GH}_2$  into atmospheres with no restrictive and reflective downstream geometry present resulted in no ignitions up to a burst pressure of 831 bar. No ignitions were observed below a cavity pressure of 8.8 bar (gauge). Ignitions always occurred above a cavity pressure of 27 bar (gauge) [955].

A large-eddy simulation model was used to describe the spontaneous ignition dynamics in a tube with a non-inertial rupture disk separating the high-pressure hydrogen storage and the atmosphere [956].

High-pressure hydrogen releases in the range of initial pressures from 20 to 275 bar and with nozzle diameters of 0.5–4 mm have been investigated using glass tubes and a high-speed CCD camera [957]. The problem was theoretically considered in terms of contact discontinuity for the case when spontaneous ignition of pressurized hydrogen due to the contact with hot pressurized air occurred. The effects of boundary layer and material properties were considered in order to explain the minimum initial pressure of 25 bar leading to the self-ignition of hydrogen with air.

The effects of the diaphragm shape and boundary layer near walls on autoignition induced by high-pressure hydrogen release in air in a real size tube were numerically studied using Navier-Stokes equations with multi-component gases [958]. The numerical results showed that there is a grid dependency that provides the optimal grid system via a comparison of the theoretical boundary layer thickness. The validity of the numerical system was confirmed by comparing the numerical and experimental precursor shock wave velocities. The initial diaphragm shape affects the hydrogen release flow structure and its autoignition mechanism. Two different autoignition styles were

observed from the numerical results: one occurred near the boundary layer owing to the induction time effect and Kelvin-Helmholtz instability and another may occur near the center axis owing to a Rayleigh-Taylor instability.

Self-ignition behavior of highly transient jets from hydrogen high pressure tanks were investigated at pressures up to 26 MPa [959]. The jet development and related ignition/combustion phenomena were characterized by high-speed video techniques and time-resolved spectroscopy, providing information on ignition region, flame head jet velocity, flame contours, pressure wave propagation, reacting species, and temperatures. On burst of the rupture disc, the combustion of the jet starts close to the nozzle at the boundary layer to the surrounding air. Combustion velocity decelerated in correlation to an approximated drag force of constant value which was obtained by analyzing the head velocity. The burning at the outer jet layer developed to an explosion converting to a nearly spherical volume at the jet head; the movement of the centroid was nearly unchanged and followed the jet front in parallel. The progress of the nearly spherical explosion could be evaluated by assuming an averaged flame ball radius. An apparent flame velocity was estimated to be about 20 m/s and it seemed to increase slightly with the pressure in the tank or the related initial jet momentum. Self-initiation was nearly always achieved especially by induced interaction of shock waves and their reflections from the orifice. The combustion process is composed of shell combustion of the jet cone at the bases with a superimposed explosion of the decelerating jet head volume.

High-pressure hydrogen can ignite spontaneously when it is abruptly released into the air. Numerical simulations were conducted for a cylindrical tube, initially filled with air, with various burst conditions and the predictions were validated by comparison with previous experimental data [960]. A maximum burst pressure of 40 MPa was simulated for two pressure boundaries characterized by spherical and flat diaphragm shapes. The results showed that there is a significant relevance between the ignition features and the burst conditions. The shock interactions induced by a spherical pressure boundary can play a role in the ignition by two separate mixing and reaction regions appearing in the core and boundary layer of the tube. The reaction in the core region can assist in the formation of a complete flame when the burst pressure is relatively low, whereas when the burst pressure is higher, it is possible to initiate the ignition by the reaction region near the boundary layer alone, even without the reaction in the core region when the burst pressure is high. The ignition patterns can differ according to the change of burst conditions and diaphragm shape.

An experimental investigation of spontaneous ignition and flame propagation at high-pressure hydrogen release used cylindrical tubes with different cross-sections: **(1)** local contraction, **(2)** local enlargement, **(3)** abrupt contraction, and **(4)** abrupt enlargement. The results showed that the presence of the varying cross-section geometries can significantly promote the occurrence of spontaneous ignition [961]. Com-

pared to a tube with constant cross-section, the minimum pressure release needed for spontaneous ignition for the varying cross-sections tubes was considerably lower. The initial ignition location was closer to the disk in the presence of varying cross-section geometries in comparison to a straight channel. As the flame emerged from the outlet of the tube, the velocity of the flame front in the vicinity of the nozzle increased sharply. Then, a deflagration developed across the mixing zone of the hydrogen/air mixture. The maximum deflagration overpressure increased linearly with the release pressure. Subsequently, a hydrogen jet flame was produced and evolved in different shapes at different release stages. A fireball was formed after the jet flame spouted into open air at the exit of the tube. Later, the fireball developed into a jet flame which drifted upward and continued to burn with updraft in the vertical direction.

Hydrogen diffusing into hot air caused by a shock wave from diaphragm rupture and entering the hydrogen-oxidizer mixed region is heated enough to start a chemical reaction. Flow visualization studies looked at spontaneous ignition in a rectangular tube [962]. The results confirmed the presence of a flame at the wall of the tube when the shock wave pressure reached 1.2–1.5 MPa in more than 9 MPa burst pressure and confirmed that ignition occurred near the wall, followed by multiple ignitions as the shock wave propagated, with the hot spots eventually combining to form a flame front.

Diaphragms with several membrane thicknesses and score patterns were ruptured in a controlled test by high-pressure hydrogen, and the formation of a shock wave in the tube was observed during a study of self-ignition of high-pressure hydrogen that was released into air through a ruptured diaphragm [963–965]. The behavior of the ruptured diaphragm and the subsequent self-ignition was photographed using a high-speed camera, while the self-emission intensity from a flame was measured using a photomultiplier. The experimental results showed that the diaphragm rupturing condition is one of the main factors affecting the self-ignition. The self-ignition caused a ring-shaped cylindrical flame that traveled downstream, along a boundary between the hydrogen jet and the shock-heated air.

In studying the effects of hydrogen additions on spontaneous ignition of high-pressure hydrogen released into hydrogen-air mixture, hydrogen and air were premixed with different volume concentrations (0, 5, 10, 15, and 20%  $H_2$ ) in the tube before high-pressure hydrogen was suddenly released [966]. Pressure transducers in the tube detected the shock waves, measured the shock wave speed and overpressure. Light sensors were used to detect the occurrence of high-pressure hydrogen spontaneous ignition in the tube. A high-speed camera was used to capture the flame propagation behavior outside the tube. It was found that only 5% hydrogen addition could decrease the minimum storage pressure required for spontaneous ignition from 4.4 to 2.8 MPa. When 10, 15 or 20% hydrogen were added to the air, the minimum self-igniting storage pressure decreased to 2.8, 1.8, and 1.8 MPa, respectively.

The self-ignition of hydrogen gas released from a high-pressure tank using discharge tubes with different diameters, the processes of flame transition at a nozzle

and jet flame development were characterized using a high-speed camera [967]. The results indicated that the intensity of a shock wave and the Mach number decay faster in a 10-mm diameter tube than that in a 15-mm diameter tube. The pressure in a 15-mm diameter tube was weaker than that in a 10-mm diameter tube at the initial stage; however, it became higher during the later stage. Spontaneous ignition was more likely to happen in a 15-mm diameter tube. The formation of a stabilized flame at the tube exit and Mach disk were observed during the transition of the flame to a jet fire. The stabilized flame showed a triangular shape because of the influence of a Prandtl-Meyer flow when a hydrogen jet entered a suddenly expanding environment. The formation and separation of a spherical flame were recorded during jet flame development. Large vortices were formed in front of the flame because of the Kelvin-Helmholtz instability, which resulted in the separation of the spherical flame. The vortices stopped rotating until the separated flame disappeared.

#### 7.9.2.4 Ignition by Adiabatic Compression

Hydrogen is unlikely to be used as a diesel fuel with compression-ignited reciprocating engines, but rapidly compressed air/hydrogen gas mixtures will ignite like diesel fuel. The spontaneous ignition of hydrogen at pressures between 3.5 and 7 MPa has been investigated in a free-piston compressor which rapidly increased the temperature and pressure of a mixture of oxygen, hydrogen, and helium [968]. Explosions occurred during the compression stroke and were detected by a piezoelectric pressure transducer. The temperature at ignition was independent of pressure, and was calculated to be approximately 1150 K. The results of a chemical kinetic analysis were in good agreement with the experiments. The kinetics analysis indicated that the ignition is most likely initiated by the breakdown of  $\text{H}_2\text{O}_2$  to the highly reactive radical  $\cdot\text{OH}$ .

#### 7.9.2.5 Autoignition of Flowing Propellant

It is unlikely that LOX and LH2 or LOX and RP-1 would autoignite upon rapid mixing, but various flow conditions potentially contributing to autoignition of flammable mixtures were investigated. An electrostatic charge might build up as a result of relative fluid motion between immiscible fuel and oxidizer [969]. A hypothesis was proposed based on two simultaneous processes: (1) mixing of the propellants, and (2) development of electrostatic charges sufficient to cause ignition sparks. This investigation included electrostatic charging effects at interfaces of mixing liquids, cosmic radiation, and heat from orthohydrogen→parahydrogen conversion. Neither of the latter two processes was considered a significant ignition mode compared to electrostatic phenomena.

## 7.10 Limits of Flammability

Limits of flammability, flammability limits may sometimes also be called limits of inflammability. They are closely related to limits of explosion and limits of detonation.

For mixtures of any particular combustible gas and air (or oxygen) there are, under given physical conditions, certain limits of composition within (but not outside of) which self-propagation of flame will occur indefinitely after ignition has once been effected. These limits, usually referred to as the “lower” and “upper” limits of flammability, respectively, at given temperature and pressure vary somewhat **(1)** with the position of the source of ignition, since the progress of the flame may be assisted or retarded by convection currents accordingly as it has to propagate in an upward, horizontal or downward direction, and **(2)** according to the size and material and wall-coating of the containing vessel.

### 7.10.1 Methods for Determination of Limits of Flammability

The limits of flammability of combustible gases and vapors in air are usually determined using the apparatus described in [970] and [971], but there are many other experimental set-ups in use. The limits of flammability will depend on the size and shape of the combustion chamber, on the direction of flame propagation, and on the ignition energy of the ignitor (Table 50).

**Table 50:** Explosion limits of hydrogen in air measured at room temperature and atmospheric pressure.

|                                               | Test method                       |             |             |            |
|-----------------------------------------------|-----------------------------------|-------------|-------------|------------|
|                                               | DIN 51649                         | EN 1839 (T) | EN 1839 (B) | ASTM E 681 |

LEL = Lower Explosive Limit, UEL = Upper Explosive Limit

Data source: [974]

NASA has a standard procedure for determination of flammability, offgassing, and compatibility, but that is mostly for combustibility of solid materials in oxygen-enriched atmospheres [972]. Other countries have similar specifications for the determination of flammable limits in air [973].

Table 50 shows that the explosion limits measured according to the 4 standard test methods show differences, which are most pronounced with the diluted (40% N<sub>2</sub>) mixtures. The procedures according to DIN 51649 and EN 1839(T) yield comparable results because the test apparatus used for both methods is very similar. The explosion range of EN 1839(T) is a little bit wider because the diameter of the explosion tube is larger so that flame quenching effects are eliminated better. The ASTM method shows a similar LEL but a lower UEL. DIN 51649, ASTM E 681, and EN 1839(T) are so-called open vessel methods. The pressure inside the test vessel during the reaction is nearly constant at atmospheric pressure and burned gases can escape through a gas outlet. The closed vessel method according to EN 1839(B) shows the largest deviations. The LEL is higher compared to the other three methods. The reason might be the pressure threshold criterion for reaction indication. It is obviously less sensitive than the visual criterion.

### 7.10.2 Limits of Flammability of Hydrogen in Air

The limits of flammability of hydrogen in air are listed in a large number of publications, often in comparison to flammable limits of other combustible gases [343, 975, 976]. Other studies examined the limits of flammability and at the same time measured the speed of flame propagation and the quenching distance of hydrogen flames. Quenching distance of hydrogen flames are discussed in Section 7.10.3.5 “Quenching Distance and Critical Diameter for Propagation of Air/Hydrogen Flames.” Transition from hydrogen combustion to hydrogen detonation is discussed in Section 7.12.7 “Deflagration-to-Detonation Transitions.”

The limits of flammability of hydrogen in air are extremely wide, from 4.0 to 74.2 vol.-% for upward propagation at room temperature and sea-level atmospheric pressure. Hydrogen has a much wider range of flammability in air (4–75% by volume) than methane (5–17% by volume), propane, or gasoline, and the minimum ignition energy (for a stoichiometric mixture) is about an order of magnitude lower (1/16th that of methane). The transition from a combustion to an explosion and eventually a detonation depends on the amount of confinement and the energy of the ignition source. In confined spaces, such as in tanks or pipes, air/hydrogen mixtures will explode or even detonate, but not in unconfined open spaces [516, 890]. The flammability properties of hydrogen are unique and different from those of any other flammable gas.

A summary on thermal hazards of selected aerospace fluids contains a detailed section on flammability hazards of gaseous hydrogen [934]. Limits of flammability were summarized for test results obtained under a wide range of conditions, including direction of flame propagation, moisture content of air, pressure, dimensions of test chamber, diluents, inhibitors, gravity or oxygen content in diluents. Also, flammability in gas mixtures with other oxidizing atmospheres was tabulated and graphed.

**Table 51:** Flammability limits of hydrogen in oxidizing atmospheres

| Conditions                                                      | Hydrogen content, vol.-% |             |                         |             |                        |             |

Note: Dashes indicate no information available. ~ indicates that tabulated values were obtained by visual interpolation of values from original graph curves.

<sup>a</sup> Tungsten electrodes were employed, but the energy of initiation was not published (Elston and Laffitte 1947).

<sup>b</sup> 45 mJ (47.5 BTU) ignition source was applied (Mills and Linley 1977).

Data source: [523, 934, 975]

Flammability limits of hydrogen in air are summarized in Table 51. This table may contain data for dry air as well as moisture-saturated air. The difference in modes of flame propagation that occurs between the upward lean limit at 4% H<sub>2</sub> and the downward lean limit near 8% H<sub>2</sub> is quite anomalous for any flammable gas. Upward propagation from a convectively rising flame kernel involves propagation into a velocity gradient induced by buoyancy forces, and at a slow but finite propagation velocity, the flame is blown out by its own buoyancy-induced flow [349].

The type of combustion of hydrogen-air mixtures near the flammability limits for different initial temperatures (from 298 to 423 K) and pressures (100 and 250 kPa) relevant was re-examined using a spherical vessel equipped with a pressure transducer to monitor the pressure increase subsequent to the combustion and with two optical windows to record the flame propagation [977]. From the schlieren images, different

regimes of flame propagation could be identified depending on the temperature and pressure. The maximum post-combustion pressure obtained experimentally has been compared to the theoretical maximum pressure for adiabatic combustion at constant volume. The flammability limits of air/hydrogen have been determined for different temperatures and pressures and were compared to the data reported in the literature.

### 7.10.3 Effect of Pressure on Limits of Flammability

#### 7.10.3.1 Effect of Reduced Pressure on Limits of Flammability in Air

The flammability of hydrogen in air at reduced pressures was studied using tubes with lengths of 96 cm (38 in.) and with diameters of 8 cm (3.2 in.), 16 cm (6.3 in.), and 25 cm (9.8 in.) [978]. An electrical spark, positioned to promote upward flame propagation, was used as the ignition source. Similar flammability tests were performed in a 2-L (122-in.<sup>3</sup>) hemispherical chamber, using a 45 mJ spark discharge at the geometric center of the hemisphere as the ignition source [979].

Reduced pressure flammability tests were performed in two cylindrical chambers, one of length 1.83 m (72 in.) and diameter 0.61 m (24 in.), and another of length 3.66 m (144 in.) and diameter 1.23 m (48 in.) [980]. The direction of flame propagation was not specified. The ignition source was a spark discharged from a capacitor bank with a maximum storage capacity of 2700 J; approximately 60–70% of the energy was delivered to the gas. The results of these investigations are shown in Figure 69.

The lowest pressure for which a low energy ignition source produced ignition was approximately 6 kPa (0.9 psia), at a hydrogen concentration of between 20 and 30 vol.-% [934]. This value was obtained in a 25-cm tube and a 2-L hemispherical chamber. The low-pressure limits were greater in the small diameter tubes.

The upper flammability limits (UFL) of air/hydrogen, air/methane, air/ethane, air/*n*-butane, and air/ethylene were determined experimentally at room temperature (293 K = 20 °C) and initial pressures of 1.0, 0.7, 0.5, 0.3, 0.1, and 0.05 atm [981]. Experiments were conducted in a closed cylindrical stainless steel vessel with an internal diameter of 10 cm and a length of 100 cm with upward flame propagation. The UFL of hydrogen was observed to be inversely proportional to the initial pressure in the range from 1.0 to 0.3 atm and proportional to the initial pressure from 0.3 to 0.05 atm. In contrast, the UFLs of the lower alkanes and ethylene decreased with the initial pressure. The average flame propagation velocities at UFL concentrations of hydrogen, methane, ethane, *n*-butane, and ethylene in air at reduced pressures were also examined. It was found that the flame propagation velocity of hydrogen was larger than those of the hydrocarbons, increased when the initial pressure decreased from 1.0 to 0.3 atm, and then decreased with further decrease of pressure. Flame propagation velocities at UFL concentrations of the hydrocarbons decreased with the initial pressure. In a parallel series of experiments, the lower flammability limits (LFLs) of

**Figure 69:** Effect of reduced pressure on limits of flammability of hydrogen in air. (Reproduced and modified from [934].)

air/hydrogen, air/methane, air/ethane, air/*n*-butane and air/ethylene were also measured in the same closed cylindrical vessel (inner diameter 10 cm, length 100 cm) under the same conditions with upward flame propagation, at room temperature (293 K = 20 °C) and initial pressures of 1.0, 0.7, 0.5, 0.3, and 0.1 atm [982, 983]. The LFL of hydrogen initially decreased with pressure from 1.0 to 0.3 atm, but then the LFL increased with further decrease of pressure. In contrast, the LFLs of the hydrocarbons increased when the pressure decreased from 1.0 to 0.1 atm, except for methane for which the LFL did not change with pressure. The adiabatic constant volume flame temperatures at the new measured LFL concentrations of hydrogen and the hydrocarbons were calculated at subatmospheric pressure conditions. The behaviors of the adiabatic flame temperatures of hydrogen and the hydrocarbons were similar to those of the LFLs under the influence of low pressures.

Under the influence of pressure, the UFL of hydrogen in air changes more than the LFL. For example, when the initial pressure decreased from 1.0 to 0.1 atm, the maximum change of the LFL was 0.2 mol-%, which is much smaller than that of the UFL which was 2.1 mol-%. For hydrogen, when the initial pressure decreases below 1.0 atm, the flammability region widens (LFL decreases and UFL increases), see Figure 70.

**Figure 70:** Flammability region of hydrogen at sub-atmospheric pressures and room temperature in air. (Reproduced and modified from [983], with permission from Dr. Thuy Minh Hai Le dated 9 March 2021.)

The region is the widest at 0.3 atm where the LFL decreases by 0.2 mol-% and the UFL increases by 2.1 mol-%. The region starts to narrow when the pressure decreases below 0.3 atm. The widening of the flammability region when the pressure decreases can be attributed to the reaction mechanism of hydrogen in which the influence of the three-body reaction

becomes weaker with decreasing pressure (Table 52). See also [984].

**Table 52:** Flammability limits of pure hydrogen and light hydrocarbons in air at atmospheric and subatmospheric pressures and room temperature.

| Initial pressure, atm |            | 1.0   | 0.7   | 0.5   | 0.3   | 0.1   |
|-----------------------|------------|-------|-------|-------|-------|-------|
| Hydrogen              | LFL, mol-% | 3.95  | 3.85  | 3.85  | 3.75  | 4.14  |
|                       | UFL, mol-% | 75.73 | 75.88 | 77.30 | 77.80 | 76.95 |
| Methane               | LFL, mol-% | 5.35  | 5.35  | 5.35  | 5.35  | 5.35  |
|                       | UFL, mol-% | 15.40 | 14.85 | 14.65 | 14.50 | 14.35 |
| Ethane                | LFL, mol-% | 2.85  | 2.85  | 2.90  | 3.00  | 3.75  |
|                       | UFL, mol-% | 14.00 | 13.64 | 12.86 | 12.37 | 11.76 |

|                       | UFL, mol-% | 30.61 | 29.49 | 27.50 | 23.39 | 19.26 |

Data source: [983]

Fundamental safety properties of air/hydrogen mixtures, such as flammability limits and laminar flame speed at subatmospheric pressures were measured in a spherical

explosion chamber with a volume of 8.2L and a high-speed camera combined with a schlieren system for flame visualization [368]. Upper and lower flammability limits and laminar flame velocity were obtained in the range of 4–80% hydrogen in air at initial pressures of 25–1000mbar. Laminar burning velocity and flame length were correlated with overall reaction order and activation energy.

The flammability of hydrogen was tested in a 20-L vessel from the pressure at sea level up to 180 mbar corresponding to an altitude of 12.2km (40000 feet) [985]. The lower and upper flammability limits were found first and compared with previous data. Then, peak explosion pressure was measured across all flammable hydrogen and oxygen concentrations. The oxygen concentration started from the concentration found in air and was reduced by adding additional nitrogen. These tests were performed up to the point where the limiting oxygen concentration was reached for each altitude. In general, as the altitude increased, the limits of flammability for hydrogen and oxygen widened, and the peak explosion pressures decreased.

### 7.10.3.2 Effect of Increased Pressure on Limits of Flammability in Air

In the early years there were some reports that increased pressure would narrow instead of widen the range of flammability of hydrogen in air for downward propagation and the results were compared to those obtained with methane instead of hydrogen. Some investigators had reported that the lower limit for hydrogen-air mixtures, which started at 7.0 vol.-% at atmospheric pressure, rose steeply with pressure up to 10.8 vol.-% at 21atm, after which it fell gradually to 8.4 vol.-% at 210 atm, with some variation depending on the intensity of the source of ignition.

In one series of experiments, the “explosion-limits” at room temperature of air/hydrogen, air/methane and air/CO mixtures have been determined from initial pressures of 1, 5, 10, 30, 50, 75, and 125 atm [986]. These early (ancient) experiments showed that the general effect of increased pressure is to widen the explosion limits of air/hydrogen, shown as solid lines in Figure 71, also in comparison to methane (dashed lines). The effect of pressure on widening the explosive limits was more pronounced for methane than for hydrogen. Pressures up to 10atm were tested in a cylindrical explosion chamber 75cm long  $\times$  5cm diameter with a capacity of 2L, fitted at each end with a quartz window, so that the explosion could be visually observed and pressures above 10atm were tested in a 240-mL spherical chamber. The source of ignition was a melting platinum fuse wire. These early experiments failed to detect the anomaly which occurs in air/hydrogen and oxygen/hydrogen mixtures at pressures below 20 bar and is shown in subsequent figures in this chapter.

The effects of elevated pressures on the flammability of hydrogen in air are shown in Figure 72 for downward propagation in tubes, and side or central ignition in a spherical chamber. The shapes of the flammability curves changed with the direction of flame propagation, and the flammable range first decreased and then increased as pressure was increased above ambient pressure. This variability was

**Figure 71:** Limits of flammability of air/hydrogen and air/methane at elevated pressures. (Republished and modified from [986], with permission of ©1928 The Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

attributed to a combination of kinetic and thermal effects [975]. Figure 72 shows the effect of increasing pressure on lower and upper limits of flammability of hydrogen in air. This image consists of two graphs with the center section omitted because it did not contain any data. This graph is based on data obtained from three different sources with equipment of different dimensions and different ignition methods. If one plots the upper limit of flammability data as a function of pressure, all three curves have a minimum in the range 1.0–1.5 MPa, regardless of the apparatus in which the measurements were made.

The upper limit of flammability is more sensitive to the type of diluent gas used than the lower limit. The upper limit of flammability of hydrogen in air, oxygen, oxygen-helium, oxygen-neon, oxygen-argon and oxygen-carbon dioxide mixtures was measured at room temperature and pressures between 98 and 2938 kPa (0.97 and 29 atm) in two cylindrical bombs with volumes of 1.5 and 5.2 L [987]. The limit in ternary mixtures was determined in 20, 40, 60, and 80% helium, 20% neon, 20% argon, and 10% carbon dioxide concentrations. The  $O_2/H_2/He$  experiments were carried out with oxygen-hydrogen-helium mixtures of 0, 20, 40, 60, and 80% helium at 0.97, 1.94, 2.98, 4.84, 9.7, 19.4, and 29.0 atm pressure. The critical oxygen concentration represents the maximum percentage of oxygen which will be safe in any unknown mixture of hydrogen with oxygen and helium at room temperature. The maximum safe percentage of oxygen in a oxygen-hydrogen-helium mixture was calculated for pressures between 98 and 2938 kPa (0.97 and 29 atm).

**Figure 72:** Limits of flammability of hydrogen in air at elevated pressures. (Reproduced and modified from [975].)

The flammability of hydrogen in air was measured at pressures up to 15 MPa (150 bar) and ignition by glow wires or sparks and the results in Figure 73 show the unusual behavior of the upper limit at pressures below 20 bar [988].

The discussion of explosion limits of oxygen/hydrogen in comparison to those of air/hydrogen may be repeated in Section 7.12.5 “Detonability Range of Hydrogen Gas in Air,” but it is started here by a juxtaposition of the explosion limits as a function of pressure graphs for the two mixture conditions with and without the presence of nitrogen. The explosion limits of oxygen/hydrogen mixtures were measured at pressures up to 200 bar and compared to the results discussed above, which were obtained with air/hydrogen at pressures up to 150 bar [988]. The upper limit of explosion for both mixtures initially goes down with increasing pressure and the lower limit of explosion goes up, resulting in a narrowing of the explosive range with increasing pressure at pressures below 20 bar [974, 989, 990]; however, once the pressure exceeds the regime of this anomaly, the opposite seems to be the case (Figure 74). The shape of the explo-

sion limit curves is the same for initial gas temperatures of 293 and 353 K (20 and 80 °C). The explosive range is wider at the higher temperature, as expected.

Air/hydrogen combustion at initial pressures of up to 3 MPa and initial temperatures of 295 K was measured in a high-pressure bomb with windows which allowed recording the UV/Vis and NIR spectra of the flames [991]. Peak pressures up to 20 MPa were recorded with a piezoelectric transducer. The pressure-time and flame radius-time curves gave the burning velocity. The burning velocity had a pressure exponent of 0.23.

### 7.10.3.3 Effect of Increased Temperature on Limits of Flammability

A study of the effects of temperature on the flammability limits for downward propagation in air/hydrogen mixtures using an electrical spark as the ignition source in a 2.5-cm (1-in.) diameter tube showed that the LFL for downward propagation decreases from 9.4 to 6.3 vol.-% and the UFL increases from 71.5 to 81.5 vol.-% as the temperature was increased from 290 to 673 K (63 to 752 °F), as illustrated in Figure 75 [992]. This figure is essentially two graphs with the center section omitted because it did not contain any data.

**Figure 75:** Effect of increased temperature on limits of flammability with downward propagation of flame. (Reproduced and modified from [975].)

When studying the effect of initial gas temperature on explosive limits (initiation in the center of a high-pressure bomb with flame propagation in all directions), the shape of the two curves (lines) is similar to those shown in Figure 75 above, but the width of the flammable range is wider, Figure 76.

**Figure 76:** Influence of the temperature on the explosion limits of air/hydrogen mixtures, measured at atmospheric pressure according to DIN 51649. (Republished and modified from [974], with permission from Bundesanstalt für Materialforschung und -prüfung dated 30 March 2021.)

#### 7.10.3.4 Influence of Type of Ignition Sources on Flammability of Hydrogen in Air

In a study of the effects of different igniters on the flammability limits for oxygen-hydrogen-nitrogen mixtures at reduced pressures, two test chambers were fabricated out of 304 stainless steel, cylindrical in configuration, with volume displacements of 0.28 and 6.9 m<sup>3</sup> (10 and 240 ft<sup>3</sup>). The ignition sources were electrical spark discharge, electrically heated wire, electrically fused wire, and an electrically heated surface [993, 994]. The results indicated that the ignitability of hydrogen decreased as pressure was decreased. The ignitable pressure limits obtained in the 0.28 m<sup>3</sup> chamber were essentially the same as obtained in the 6.9 m<sup>3</sup> chamber; however, the lower flammability limits observed in the 6.9 m<sup>3</sup> chamber were significantly lower than those observed in the 0.28 m<sup>3</sup> chamber. The electrically heated wire igniter produced the lowest ignitable pressure limits at the higher hydrogen concentrations, whereas the spark igniter produced the lowest ignitable pressure limits at the lower hydrogen concentrations. The lowest ignitable hydrogen quantity was 4.25 vol.-% whereas the lowest oxygen quantity that supported an ignition was 4 vol.-%. Increasing the electrical spark discharge energy from 10 to 5000 joules resulted in a decrease of the ignitable pressure limit. Increasing the initial temperature of the gas mixture from -40 to 300 °F also produced a decrease in the ignitable pressure limit.

The oxygen concentration in these mixtures was 6 vol.-% for hydrogen concentrations of 10 vol.-% or less, and 6/10 of the hydrogen concentration at higher concentrations. This procedure ensured that the oxygen concentration always exceeded that required for stoichiometric oxidation. Figure 77 shows the lower flammability limit observed for each igniter as a function of pressure.

**Figure 77:** Effects of type of ignition source and pressure on the LFL for oxygen-hydrogen-nitrogen. (Reproduced and modified from [934].)

At hydrogen concentrations just below the observed lean limits, the heated wire and heated surface, which deliver their energy over a relatively long period of time, produced hydrogen burning at the igniters; however, the flames did not propagate and self-extinguished when the power to the ignition source was discontinued. This type of non-propagating burn was observed at the lean limits for pressures above 1.4 kPa (0.2 psia). A similar phenomenon has been observed when heated surfaces (glow plugs) were used to burn hydrogen in a controlled preventive manner at concentrations below the LFL, thus preventing leaks in enclosed areas from attaining flammable or explosive concentrations.

#### 7.10.3.5 Quenching Distance and Critical Diameter for Propagation of Air/Hydrogen Flames

Flames are quenched by excessive loss of heat or active particles or both, to adjacent walls. Experiments have shown that flames in a mixture of given temperature, pressure, and composition cannot pass through openings smaller than some minimum size. This size is the quenching distance. Its actual magnitude depends on the geometry; for instance, the minimum diameter for a cylinder is greater than the minimum separation distance of parallel plates. The geometrical relations among quenching distances for ducts of various shapes have been worked out theoretically and agree quite well with experimental results (From Refs. 35 and 36 in [343]).

### Effect of Mixture Composition on Quenching Distance

In Figure 78 quenching distances (minimum separation of parallel plates) are plotted against fuel concentration [343]. The data were obtained in connection with measurements of ignition energy. The curves show minimum quenching distances at or near stoichiometric composition. The minimum quenching distance at 1 atmosphere and room temperature is 0.063 cm. The knowledge of quenching distances is important for the design of flashback arrestors and detonation traps in air/hydrogen or oxygen/hydrogen gas mixtures.

**Figure 78:** Effect of hydrogen concentration on quenching distance of air/hydrogen mixtures. (Reproduced and modified from [343], based on data from Lewis and von Elbe 1951)

#### 7.10.4 Limits of Flammability of Hydrogen in Oxygen

The limits of flammability of hydrogen in undiluted oxygen are substantially wider than the limits of flammability of hydrogen in air. For upward flame propagation, the flammable range of hydrogen in oxygen extends from 4.1 to 94.0 vol.-% H<sub>2</sub>, and the limits for downward propagation are not much different.

Diluents like nitrogen, argon or helium will narrow the flammable range of hydrogen with oxygen, both at atmospheric pressures and above or below atmospheric pressures.

The parameters of spark ignition of hydrogen in oxygen/nitrogen mixtures affected by cryogenic temperatures are breakdown voltage, quenching distance, flammability limit, and spark ignition energy. Analytical methods for predicting values of most spark ignition parameters for engineering application are cumbersome and far-fetched. Very few data were available in the literature on ignition at cryogenic temperatures. The ignitability of gaseous  $O_2/H_2/N_2$  mixtures at 100 K was tested with a glow plug igniter in a closed bomb at 34.4, 101, and 274 kPa (0.34, 1.0, and 2.7 atm). Data were compared to results of tests conducted at standard conditions, 289 K and 101 kPa (520°R and 14.75 psia) [995].

Experimental studies were carried out to determine the quantities of helium or nitrogen needed for suppressing ignition of mixtures of oxygen with hydrogen under conditions of turbulent flow in a 15-cm (6-in.) diameter tube [996]. The results indicated that on a weight basis the order of effectiveness of the various agents was  $He \gg N_2$ . The quantities of inerting agents required were large enough to preclude widespread in-flight applications to inert leakage once it is detected. The principal utility of inerting processes is probably only in connection with fire prevention during static firing and prelaunch operations on the ground.

Flammability limits of hydrogen-oxygen-diluent mixtures were determined in a 5-cm diameter, 1.8-m long tube, for upward, downward and horizontal propagation of the flame [997]. It was found that for fuel-lean mixtures, upward propagation limits were nearly independent of the diluent type and concentration, but downward limits showed a slight dependence on diluent type and concentration. Limits for fuel-rich mixtures were independent of the direction of propagation of the flame. In all cases, to a good approximation, horizontal limits lay midway between the upward and downward limits. Limits for fuel-rich mixtures were very dependent on the oxygen volume fraction.

Flammability limits in oxygen/hydrogen/inert diluent (helium, argon, carbon dioxide, steam) mixtures at temperatures up to 523 K and pressures up to 2 MPa as well as of the burning velocities of  $O_2/H_2/N_2$  mixtures at 293 K and 4 MPa were measured in a vertical cylinder 50 L in volume (diameter 30 cm and height 80 cm) [998]. The mixture was ignited by fusion of a heated nichrome wire. An anomalous effect of helium on the lower flammability limit in an oxygen-hydrogen-helium mixture was noted. There was a synergistic effect for helium-carbon dioxide and helium-steam mixtures used as inert retardants. The data were interpreted theoretically on the assumption of the important role played by the selective diffusion of hydrogen and helium from the initial mixture into the flame. See also [999].

### 7.11 Radiation from Hydrogen Flames

The heat radiation of an air/hydrogen flame is only 1/10 of the radiation intensity of a hydrocarbon flame. Firefighting crews can operate closer to a hydrogen fire without getting scorched by heat radiation. A hydrogen fire does not expand as rapidly to adjacent combustible structures as a hydrocarbon fire. A pool of burning liquid hydrogen is consumed in 1/10 of the time of a pool of gasoline or kerosene of the same volume. The emission spectrum of hydrogen flames was already described in Section 3.2.4 “Radiation Emission Spectra of Oxygen/Hydrogen Flames.”

The emissivity of a hydrogen flame is only 0.09 compared to the emissivity of a black body radiator which is close to 1.0. Radiation measurements showed that persons could approach a large hydrogen fire for 30 s to as close as 54 m without suffering heat burns [497, 499]. Atmospheric moisture absorbs thermal energy radiated from a hydrogen fire and can reduce the radiation values recorded from laboratory experiments in dry air.

In a study of the structure and radiation properties of round turbulent hydrogen/air diffusion flames, measurements were made of mean and fluctuating stream-wise velocity, mean temperatures, species concentrations, spectral radiation intensities, and radiant heat fluxes [1000]. The measurements were used to evaluate predictions based on the laminar flamelet concept and narrow-band radiation models, both ignoring (using mean properties) and considering effects of turbulence/radiation interactions. Physical property state relationships found by correlating auxiliary measurements in laminar flames proved to be almost equivalent to conditions for local thermodynamic equilibrium. The agreement of structure and radiation predictions was reasonably good. Effects of turbulence/radiation interactions were significant for these flames, causing almost a 100% increase in spectral radiation intensities, in comparison to mean property predictions upstream of the flame tip.

Burning hydrogen emits heat radiation effected by broad water bands in NIR and IR spectral ranges. In the case of large cloud explosions, the risk of heat radiation is commonly underestimated due to the non-visible flame of hydrogen-air combustion. Organic vapor and particulate contaminants entrained into the flames will contribute to the intensity of heat radiation [1001]. Different hydrogen-air mixtures were ignited in a closed vessel and the combustion was observed with fast scanning spectrometers using a sampling rate up to 1000 spectra/s. In some experiments, to take into account the influence of organic contaminants, a spray of a liquid glycol-ester or milk powder was added to the mixture to enhance the radiation signature. During hydrogen combustion,  $\cdot\text{OH}$  free radicals emit an intense spectrum at 306 nm. This intermediary radical allows monitoring the reaction progress. Intense water band systems between 1.2 and 3  $\mu\text{m}$  emit remarkable amounts of heat radiation at a measured flame temperature of 2000 K. At this temperature broad optically thick water bands between 4.5 and 10  $\mu\text{m}$  contribute only scarcely to the total heat output.

Measurements were performed in large-scale vertical flames to characterize the dimensional and radiative properties of an ignited hydrogen jet [1002]. Visible and IR video and UV flame luminescence imaging were used to evaluate flame length, diameter, and structure. Radiometer measurements allowed determination of the radiant heat flux from the flame.

The radiative characteristics of large-scale (visible length 1.4–9.1 m) hydrogen jet flames that simulate an accidental leak from a high-pressure hydrogen container were compared with previous experimental and theoretical results for laboratory-scale non-sooting flames [1003]. The comparison showed that correlations of radiative heat fraction with global residence time need to account for the differences in thermal emittance of combustion gases for different fuels. This correction was found to be particularly important when hydrogen flames were compared to flames with  $\text{CO}_2$  as a radiation-emitting product species. The radiative fraction of large-scale jet flames was found to be smaller than that predicted by the correlation obtained for laboratory-scale flames. This was explained by an increase in optical thickness as the flame size increases.

Jet flames originating from high-pressure sources up to 413 bar (6000 psi) were studied to verify the application of correlations and scaling laws based on lower-pressure subsonic and choked-flow jet flames [1004]. These higher pressures were expected to be typical of the pressure ranges in future hydrogen storage vessels.

The dimensions of hydrogen jet diffusion flames in air formed by release of high-pressure hydrogen gas from circular nozzles with diameters ranging from 0.1 to 4 mm and release pressures from 0.01 to 40 MPa (gauge) were measured [1005]. The blow-off limits were determined as a function of nozzle diameter and feed pressure. The flame sizes were measured, and experimental equations were obtained for the length and width of the flames. The flame sizes depended not only on the nozzle diameter but also on the feed pressure. The heat radiation from the hydrogen flames could be predicted from the flow rate of the gas and the distance from the flame.

Open hydrogen flames were observed with feed pressures from 900 bar down to 1 bar (gauge) with orifices ranging from 1 to 3 mm. These data can be used to derive scaling laws about the main flame characteristics and about some thermodynamic aspects of hydrogen releases under high pressure [1006].

The temperature, velocity, turbulence and concentration distribution of hydrogen flames with different circular nozzle diameters and reservoir conditions of horizontal cryogenic hydrogen gas jets at temperatures of 35–65 K and pressures from 0.7 to 3.5 MPa were investigated [1007]. Combustion experiments of burning hydrogen jets included investigations on the stability of the flame and its propagation behavior as a function of the ignition position. Then combustion pressures and heat radiation from the sonic jet flame during the combustion process were measured. Safety distances were evaluated and an extrapolation model to other jet conditions was proposed to quantify the hazard potential arising from leaks and fires in liquid hydrogen reservoirs.

In the past, analytical methods used to establish thermal radiation hazard safety boundaries from ignited hydrogen plumes were based on models previously developed for hydrocarbon jet fires. Radiative heat flux measurements of small-scale and medium-scale hydrogen jet flames (i.e., visible flame lengths <10 m) compared favorably to theoretical calculations provided corrections were applied to correct for the product species thermal emittance and the optical flame thickness [1008]. Flame radiation measurements from two larger scale hydrogen jet flames were made to determine the applicability of current modeling approaches to these larger flames. The horizontally orientated releases were from 20.9 and 50.8 mm ID pipes with a nominal 60 bar gauge source pressure and respective mass flow rates of 1.0 and 7.4 kg/s. Care was taken to ensure no particles were entrained into the flame, either from the internal piping or from the ground below. Radiometers were used to measure radiative heat fluxes at discrete points along the jet flame radial axis. The estimated radiant fraction, defined as the radiative energy escaping relative to chemical energy released, exceeded correlation predictions for both flames.

The flame velocities of unconfined air/hydrogen gas explosions depend on the cloud size and the distance from the initiating source, related to turbulence generated by the propagating flame front. The molecular absorption bands in the flame front are exposed to continuously increasing radiation intensity of water emission bands from the interior of the reaction product fireball. The air/hydrogen flame propagation in 1-m diameter balloons was observed by high-speed video techniques including time resolved spectroscopy in the UV-Vis-NIR spectral range with a time resolution up to 3000 spectra/s [356, 1009]. Ignition, flame head velocity, flame contours, reacting species and temperatures were evaluated. Flame front velocities were found to be between 16 and 25 m/s. The flame front is not smooth, having cellular structures. The radiation of various bands from the fireball absorbed by the reacting species is estimated to have an influence on the flame velocity depending on the distance from initiation. Evaluation of OH-band and water band spectra might indicate higher temperatures of the flame front induced by radiation of the fireball [1010].

Deflagration phenomena in air/hydrogen mixtures initially filled in 1.4-m<sup>3</sup> spherical latex balloons were measured using a high-speed digital video camera and pressure transducers [1011]. A maximum flame propagation velocity of about 100 m/s was observed with a maximum overpressure of 15 kPa at 1 m from the ignition point. According to the detailed flame propagation velocity records, there were long deceleration durations. The observed maximum overpressure was smaller than the overpressure estimated on the basis of the observed maximum flame propagation velocity and the pressure wave theory of spherical flames.

High-speed cinematography in combination with image processing techniques, background-oriented schlieren technique and a difference method were used to visualize the shape of burning hydrogen jets [1012]. The combustion zone was recorded by a high-speed IR camera. The IR camera was synchronized with a rotating filter wheel to generate four different motion pictures at 100 Hz each on a defined spectral range.

The experiments provided detailed information that might be used for improving jet fire model predictions.

## 7.12 Explosion Hazards of Hydrogen

This section deals with explosions and detonations of hydrogen in air or in oxygen. There is primarily the concern about accidental explosions of hydrogen leaks in air, but there are also many practical applications of hydrogen detonations, such as drivers in shock tubes, in pulsed detonation engines, and rotating detonation engines.

A detonation explosion is capable of causing much greater physical damage to the environment due to the significantly higher shock pressure that is generated (a detonation creates as much as 20 times the initial stoichiometric pressure versus about 8 times the initial pressure for a deflagration).

### 7.12.1 Gaseous Air/Hydrogen Detonations

Spherical detonations in gas-filled balloons were initiated in a range of mixtures of hydrogen and air, at one atmosphere initial pressure, by tetryl charges with masses of 0.78–2.40 g [1013]. Due to the small size of the detonation vessel ( $= 1.5 \text{ m}^3$ ), they were limited to a maximum charge weight of only 2.4 g of tetryl and were able to initiate detonation in a stoichiometric air/ $\text{H}_2$  mixture (29.6 vol.-%  $\text{H}_2$ ) with a charge of 1.1 g of tetryl. By kinetic modeling, they estimated that a charge of 10 g of tetryl (heat of detonation  $= 4.27 \text{ kJ/g}$ ) would initiate mixtures in the concentration range from 22.7 to 49.1 vol.-%  $\text{H}_2$ , whereas for a 100 g charge, the corresponding range would be from 17.3 to 56.5 vol.-%  $\text{H}_2$ . The results were similar to those from earlier experiments by Cassutt [927], but contrary to predictions by Lee [1014, 1015]. A theoretical model embracing the full kinetic scheme for hydrogen oxidation was made to fit the experimental detonability data and can predict the variation of detonability with concentration over a much wider range. An important conclusion from the model study was that it predicts for the first time for spherical detonation the existence of concentration limits to detonability. A kinetic explanation is offered for these limits, which are approximately in the range of 13–70 vol.-% hydrogen in air.

The hazards due to deflagrative air/hydrogen blast waves were experimentally evaluated using three different sizes of latex balloons ranging from 5.4 to 1400 L [1016]. The rate of development of flame velocity and blast pressure were monitored simultaneously as a function of equivalence ratio ( $\phi = 0.5\text{--}4.0$ ), diameter of the balloon ( $d = 65$  or  $150 \text{ cm}$ ), ignition point, and ignition timing. In some tests the balloon was cut open just before the igniter was activated. In other tests ignition occurred in the center and the balloon burst as the result of overpressure from the inside.

The overpressure created by air/hydrogen explosions and detonations can be very destructive and depends on the composition and size of the air/hydrogen cloud, the degree of confinement and the mode of initiation [523]. See Section 7.12.8.1 “Overpressure from Unconfined Air/Hydrogen Explosions.”

The explosion characteristics of air/hydrogen mixtures including the maximum explosion pressure, deflagration index, the exponent parameter of the burning velocity and the burning parameter were measured in a 20-L sphere [1017]. Methods and equations are provided to estimate these parameters.

The experimental maximum explosion pressure agreed with the theoretical value estimated using a chemical equilibrium program if the concentration of hydrogen was from 10 to 75% in air, but not close to the flammable limits. The deflagration index for air/hydrogen mixtures, even if normalized by the cube root of the volume of explosion vessel, was found to be sensitive to the vessel volume. The maximum deflagration index in a 20-L explosion vessel was  $970 \text{ bar m s}^{-1}$  at 36 vol.-% of hydrogen in air. Other investigators have shown that it increases with the volume of the explosion vessel. The apparent burning velocity increased as the pressure increased during the explosion. The burn rate exponent was 0.45 for air/hydrogen mixtures. The maximum value of the burning rate occurred at about 40 vol.-% of hydrogen in air, which was above the stoichiometric concentration of 29.6 vol.-%  $\text{H}_2$ .

The critical energies of ignition of some gaseous fuels and oxygen mixtures at different initial pressure and equivalence ratios were measured [1018]. The determination of direct initiation of detonation was based on the overpressure signal from a pressure transducer. The effective energy responsible for the direct initiation was considered as the first quarter cycle of the current discharge. The effect of initial pressure and equivalence ratio on the critical energy of direct initiation was investigated in some typical gaseous oxygen and fuel (i.e.,  $\text{H}_2$ ,  $\text{C}_2\text{H}_2$ ,  $\text{C}_2\text{H}_4$ ,  $\text{C}_3\text{H}_8$ ) mixtures. It was shown that the relationship between critical energy and initial pressure is inversely exponential and it is U-shaped between critical energy and equivalence ratio.

### 7.12.2 Explosion Velocity and Overpressure of Unconfined Air/Hydrogen Mixtures

Unconfined air/hydrogen mixtures will deflagrate, but not detonate. The overpressure of such events is less than that experienced with detonations in confined spaces.

Large eddy simulation modelling of unconfined large-scale explosions were compared to results from a large air/hydrogen deflagration experiment in a 20-m diameter hemispherical polyethylene shell in the open [1019]. Two combustion sub-models, one developed on the basis of the renormalization group theory and another derived from the fractal theory, were applied. Both sub-models included a sub-grid scale model of the turbulence generated by flame front itself based on theory and observations by others on a critical distance for transition from laminar to detonative flame propagation regime. The best fit flame propagation dynamics were obtained for the fractal sub-model with a fractal dimension  $D = 2.22$ . The fractal sub-model reproduced the

experimentally observed flame acceleration during the whole duration of explosion, accurately simulating the negative phase of the pressure wave but overestimating by 50% the positive phase amplitude. The other sub-model was closer to the experiment in predicting the positive phase but under-predicted by 30% the negative phase amplitude. Both sub-models simulated experimental flame propagation up to 20 m and pressure dynamics up to 80 m with reasonable accuracy.

The blast wave in rich air/hydrogen mixtures dramatically accelerates in its later stage. The intensity of the blast wave is strongly affected by flame speed acceleration. The flame propagation behavior and the intensity of the blast wave by an accidental explosion of an air/hydrogen mixture in an open space were measured simultaneously using a soap bubble method [1020]. The blast wave in lean hydrogen mixtures grew rapidly with time because of the diffusional-thermal instability. The results showed that the flame in lean hydrogen-air mixtures was propagated by spontaneous flame instabilities. The flame in rich hydrogen-air mixtures propagated smoothly in the early stage and was intensively wrinkled and accelerated in the later stage by different types of instabilities. The flame wrinkling in the later stage of rich hydrogen flames was triggered when the flame approached the non-uniformity transition region of concentration distribution. The intensity of the blast wave of air/hydrogen mixtures was strongly affected by the acceleration of the flame propagation by these spontaneous flame disturbances.

Air/hydrogen mixtures of various concentrations were filled in a plastic tent of thin vinyl sheet of  $1\text{ m}^3$  and ignited by an electric spark [1021]. Flame behavior and blast waves generated during unconfined hydrogen deflagrations were studied using IR photography. IR photography enabled expanding spherical flame behaviors to be measured and flame acceleration exponents to be evaluated. The onset of accelerative dynamics on the flame propagation was analyzed by the time histories of the flame radius and the stretched flame speed. The results demonstrated that the self-acceleration of the flame, which was caused by diffusional-thermal and hydrodynamic instabilities of the blast wave, was influenced by hydrogen deflagrations in unconfined areas and the overpressure rapidly increased with time. The burning velocity acceleration was greatly enhanced with spontaneously formed turbulence.

The existing methods for calculating overpressure resulting from a vapor cloud explosion (VCE) were tested for their ability to predict overpressures from unconfined hydrogen explosions [1022]. Examining data collected from five reported experimental investigations on open air/hydrogen explosions covering  $1.4\text{--}300\text{ m}^3$  volume of air/hydrogen mixtures and concentrations of 20–57 vol.-%  $\text{H}_2$  showed that the existing VCE models were grossly inadequate for predicting the overpressure generated by unconfined hydrogen explosions. A new method was developed for assessing overpressures from hydrogen explosions for a given concentration and volume of release which had a much better ability to fit the experimental data, hence much stronger ability to accurately forecast the severity and consequences of hydrogen-based VCEs.

### 7.12.3 Required Minimum Initiation Energy for Air/Hydrogen Detonations

If initiated by a source other than a transition from deflagration to detonation in confined spaces, the energy required to reproducibly initiate detonations in air/hydrogen mixtures is dependent on the air : hydrogen mixture ratio. Figure 79 shows the amount of tetryl booster charge required to initiate detonations in air/hydrogen mixtures as a function of the volume percent hydrogen in air [1023]. A similar correlation can be shown for the detonation cell size determined with a sooted foil in the detonation chamber.

**Figure 79:** Minimum initiation energy for direct detonation of air/hydrogen mixtures. (Reproduced and modified from [1023].)

Experimental measurements of cell size  $\lambda$  for air/hydrogen/carbon dioxide mixtures for hydrogen/air volume ratios between 0.16 and 1.5 and carbon dioxide mol fractions of 0, 0.05, 0.10, and 0.15 showed that the cell sizes are at a minimum for both diluted and undiluted air/hydrogen mixtures near stoichiometric composition (i.e., hydrogen/air = 0.4) [1023, 1024]. Minimum cell sizes for carbon dioxide mol fractions of 0, 0.05, 0.10, and 0.15 were 1.51, 2.05, 4.2, and 15.0 cm, respectively. Results of large-scale and small-scale critical tube diameter ( $d_c$ ) measurements were presented and showed good agreement with the empirical scaling law,  $d_c = 13\lambda$ . Mean detonation velocities and pressures were measured and compared to the theoretical Chapman-Jouguet (C-J) values.

The minimum required critical energy for direct initiation of spherical detonations in stoichiometric oxygen/hydrogen mixtures at elevated pressures up to an initial pressure of 20 atm in a spherical bomb was measured to look at the effect of explosion limits on the detonation sensitivity [1025]. Direct initiation was achieved via spark ignition from a high-voltage capacitor discharge. At elevated initial pressure, the second explosion limit effect plays a significant role leading to slow-branching

reactions and the detonation sensitivity of hydrogen mixtures is comparable to other common hydrocarbon mixtures under such conditions.

Critical conditions for the direct initiation of self-sustained detonation in cold gaseous oxygen/hydrogen mixtures were examined experimentally [1026]. These initial conditions were expected to depend mainly on four parameters: the equivalence ratio of the mixture, the amount of the initial energy deposition, the initial temperature and pressure of the mixture. These critical conditions were determined by fixing alternatively three of these parameters and varying the fourth one from subcritical to supercritical detonation conditions. Results were presented for initial pressures  $P_0$  and equivalence ratios  $\Phi$  ranging from 0.3 to 1 bar and from 1 to 2, respectively, for the two initial temperatures  $T_0$ , 123 and 293 K. Detonations were initiated via an exploding wire considered as a point source of energy. The results included: **(1)** the critical initial pressures and equivalence ratios for a given initiation energy, **(2)** direct measurements of the critical energy for given initial conditions, and **(3)** cell sizes measurements in both ambient and low temperature cases. In order to bracket the critical condition, when the critical condition needed for the initiation of a self-sustained detonation was reached, the procedure was carried out at least a second time. The results indicated that for the lowest values of the initial pressure, a decrease of initial temperature may favor the onset of detonation. For most of the initial conditions, the measured detonation pressures and velocities were in agreement with C-J values computed using the ideal-gas equation of state.

The common method for measuring spark ignition energy uses a measured amount of electrical energy in the form of a short-duration capacitance discharge spark which is introduced very rapidly into a mixture of given pressure, temperature and composition and with a given electrode separation. The smallest energy that will ignite the mixture is found, and the process is repeated for other electrode spacings to find the gap for which the energy is lowest. Figure 80 is a plot of ignition energy in millijoules against fuel concentration for mixtures at room temperature and several pressures [343, 1027]. The 1-atmosphere curve indicates a minimum energy of 0.019 mJ at about the stoichiometric mixture and rises steeply toward the lean and rich flammability limits.

#### 7.12.4 Critical Diameter for Propagation of Air/Hydrogen Detonations

Knowledge of the critical diameter for propagation of detonations is required for the design of flame arrestors and detonation arrestors. The critical diameter is the diameter of tubing or orifices below which detonation from a donor section cannot propagate into an acceptor section of detonable gas.

An experimental study to investigate the transmission of a planar detonation wave through an orifice into an unconfined medium used mixtures of  $O_2 + 2H_2 + \beta N_2$  for a range of nitrogen concentrations corresponding to  $1 \leq \beta \leq 3.76$  and at an initial pressure of 1 atm [1028]. It was found that the critical diameter for the transmission

**Figure 80:** Spark ignition energies for air/hydrogen mixtures at various pressures. (Reproduced and modified from [343].)

through an orifice was identical to that for a straight tube and both followed the empirical correlation of  $d_c \cong 13\lambda$ . The transmission through square, triangular, elliptical, and rectangular orifices has led to the development of a correlation based on the effective diameter similar to the case of circular geometry (i.e.,  $d_{\text{eff}} \cong 13\lambda$ ). The effective diameter was defined as the mean value of the longest and shortest dimensions of the orifice shape. The effective diameter correlation suggested that the criterion for transmission may be based on the mean curvature of the wave front, the implication being that it is not to exceed a certain critical value. The results suggested that local properties in the immediate vicinity of the wave front are the controlling parameters for reinitiation rather than the properties of the gas dynamic flow structure in the wake.

The critical diameter for propagation of air/hydrogen detonations is related to the detonation cell width that is often determined by placing a sooted metal foil along the wall of a detonation test chamber. The cell width  $\lambda$  is an intrinsic length scale that characterizes detonations. Highly detonable mixtures have small cell widths, while

increasingly less detonable mixtures have increasingly larger cell widths. An empirical correlation exists between the critical diameter of round tubing through which detonation can no longer propagate and the cell width measured on the sooted plates

$$d_c = 13\lambda$$

The diamond-shaped pattern on the sooted foil is the result of a three-dimensional transverse wave structure which is the direct consequence of the non-linear coupling of the exothermic chemical reactions and the shock-induced hydrodynamic flow field. The critical diameter of air/hydrogen detonations is at a minimum for stoichiometric air : hydrogen ratios (Figure 81).

**Figure 81:** Minimum dimensions of air/GH<sub>2</sub> mixtures for detonation at 101.3 kPa and 298 K. (Reproduced and modified from [1023].)

A 43-cm (17-in) inside diameter, 13-m (43-ft) long heated tube was used to study detonations in air/H<sub>2</sub>/steam mixtures [1029]. Detonation cell width and velocity results were measured for air/H<sub>2</sub> mixtures, undiluted (Figure 82) and diluted with CO<sub>2</sub> or H<sub>2</sub>O for a range of H<sub>2</sub> concentrations, initial temperatures, and pressures. The results showed that the cell width is at a minimum for stoichiometric mixtures and that addition of either CO<sub>2</sub> or H<sub>2</sub>O significantly increased the detonation cell width and hence reduced the detonability of the mixture. The results also showed that the detonation cell width was reduced (detonability was increased) for increased initial temperature and/or pressure. Using a larger diameter tube, it was discovered that air/H<sub>2</sub> will detonate for a wider range of concentrations than previously believed because a mixture as lean as 13 vol.-% H<sub>2</sub> has detonated. The abbreviation HDT stands for Heated Detonation Tube, a 43-cm-diameter detonation tube at Sandia National Laboratory. The image based on data from Lee et al. [1023] is shown as Figure A2.8 on page A43 of Gregory, NASA Safety standard for hydrogen and hydrogen systems [305].

**Figure 82:** Detonation cell width of air/hydrogen detonations. (Reproduced and modified from [1024].)

For pure or diluted air/H<sub>2</sub> mixtures, the variation of cell size as a function of hydrogen concentration exhibited a characteristic U-shaped curve with a minimum around the stoichiometric composition (29.6 vol.-% H<sub>2</sub>). For air/H<sub>2</sub> mixtures at NTP initially, the cell size increased from  $\lambda = 1.5$  cm for the stoichiometric composition to  $\lambda = 1.03$  m for the leanest mixture tested (13.6 vol.-% H<sub>2</sub>) and  $\lambda = 1.35$  m for the richest mixture tested (70 vol.-% H<sub>2</sub>) [1024].

Gaseous detonation propagation phenomena are characterized by cellular structure and cell size, detonation initiation threshold, transmission, attenuation, and failure. Experimental measurements of cell size  $\lambda$  for air-hydrogen-carbon dioxide mixtures in the hydrogen/air volume ratios ranging between 0.16 and 1.5, showed that cell sizes were a minimum for both diluted and undiluted hydrogen-air mixtures near stoichiometric ratios (i.e., hydrogen/air = 0.4) [1023]. Results of large-scale and small-scale

critical tube diameter ( $d_c$ ) measurements showed good agreement with the empirical scaling law,  $d_c = 13\lambda$  for round tubing and  $d_c = 11\lambda$  for square tubes. Detonation velocities and pressures were measured and compared to the theoretical Chapman-Jouguet values. The critical tube diameter for air/ $H_2$  mixtures varies with fuel concentration as plotted in Figure 83, and exhibits the same U-shape dependence as the detonation cell size data from which it has been derived using the empirical correlation  $d_c = 13\lambda$ .

As shown in Figure 83, good agreement can be achieved between the direct measurements of  $d_c$  and the estimated values from the  $d_c = 13\lambda$  relationship. For stoichiometric composition, a critical tube diameter of the order of 20 cm was directly measured in small-scale tests in good agreement with the value  $d_c = 19.6$  cm estimated from the  $d_c = 13\lambda$  correlation using the value  $\lambda = 1.51$  cm directly measured from smoked foil records. For off-stoichiometric mixtures, direct measurements of  $d_c$  in large-scale experiments were carried out in tubes of diameters 76, 91, and 121 cm. The critical hydrogen concentrations were 21 and 51 vol.-%  $H_2$  for the 76-cm-diameter tube, 19.2 and 53.3 vol.-%  $H_2$  for the 91-cm diameter tube, 18.1 and 55.5 vol.-%  $H_2$  for the 121-cm diam-

**Figure 83:** Variation of critical tube diameter with fuel percentage in air/ $H_2$  mixtures at NTP. (Reproduced and modified from [1024].)

eter tube. As shown in Figure 83, these large-scale results fall into the range predicted by cell size data using the  $d_c = 13\lambda$  correlation.

Diluting air/H<sub>2</sub> mixtures with CO<sub>2</sub> at NTP decreased the detonation sensitivity. For example, the addition of 5, 10, and 15 vol.-% CO<sub>2</sub> to a stoichiometric air/H<sub>2</sub> mixture (29.6 vol.-% H<sub>2</sub>) increased the cell size by factors of 1.5, 2.8, and 12.8, respectively. Diluting with steam air/H<sub>2</sub> mixtures at 373 K (100 °C) and superatmospheric pressure initially caused a reduction in detonation sensitivity. For example, the addition of 10, 20, and 30 vol.-% steam to a stoichiometric air/H<sub>2</sub> mixture at 373 K (100 °C) initially increased the detonation cell size by factors of 6, 30, and 60, respectively.

In studying the influence of steam and carbon dioxide diluents on the detonability of air/hydrogen mixtures, data were obtained on the detonation cell width in a heated detonation tube that was 0.43 m in diameter and 13.1 m long [1030]. The detonation cell widths were correlated using a characteristic length calculated from a chemical kinetic model. The addition of either diluent to an air/hydrogen mixture increased the cell width for all equivalence ratios. For equal diluent concentrations, however, carbon dioxide not only yielded larger increases in the cell width than steam, but its efficacy relative to steam was predicted to increase with increasing concentration. The range of detonable hydrogen concentrations in an air/hydrogen mixture initially at 1 atm pressure was found to be between 11.6 and 74.9 vol.-% for mixtures at 293 K (20 °C) and between 9.4 and 76.9 vol.-% for mixtures at 373 K (100 °C). The detonation limit was between 38.8 and 40.5 vol.-% steam for a stoichiometric air/hydrogen/steam mixture initially at 373 K (100 °C) and 1 atm.

Detonation cell widths for stoichiometric oxygen-hydrogen-diluent mixtures in a 15-cm diameter, 7.5-m-long, steel pipe with helium, carbon dioxide, steam, and argon as diluents were measured for initial temperatures from 293 to 373 K (20–100 °C), initial pressures from 200 to 160 kPa, and hydrogen concentrations up to 60% by volume [1031]. Experiments conducted over a range of hydrogen concentrations indicated that detonation was possible down to flammability limits for certain mixtures. Over the range investigated, the initial temperature appeared to have no significant effect on the cell width. It was attempted to develop an empirical correlation to predict the cell width.

In order to design combustion chambers for detonating engines, specifically pulse detonation engines and rotating detonation engines, the cell size of detonation waves is needed. Higher than atmospheric mixture pressure detonation cell sizes are important for scaling the combustion chambers, and only few data existed for air/hydrogen detonation cell sizes at mixture pressures up to 1 MPa (10 atm). A new detonation cell size measurement technique was used to measure 15 cases for varying mixture pressures up to 1 MPa (10 atm) and different equivalence ratios [1032]. An increase in mixture pressure decreased detonation cell size and a decrease in equivalence ratio from stoichiometric composition increased detonation cell size. The experimental results were used to establish a correlation that estimated air/hydrogen detonation cell sizes given initial mixture pressures and equivalence ratios.

### 7.12.5 Detonability Range of Hydrogen Gas in Air

The detonability range of air/hydrogen gas mixtures depends on the air : hydrogen ratio, the mode of initiation, and the degree of confinement [1033]. In the wake of water-cooled nuclear reactor loss of coolant and melt-down incidents like Three Mile Island and Fukushima Daiichi, where zirconium cladding reacted with steam to create clouds of hydrogen gas inside the containment structure that later ignited and exploded, there have been many studies of air/hydrogen detonations in enclosed structures. The results of these studies in the nuclear industry would also help to examine the hazards of hydrogen explosions in rocket propellant test facilities.

Older data on detonation limits were obtained in small diameter tubes, usually 2.5 cm (1 in.) or less in diameter. One must remember that the old values represented the limit of propagation for that diameter tube. Larger tubes have produced wider limits. Several experimental studies that were completed following the Three Mile Island incident showed that the classical literature 18 and 59% detonation limits in dry air/H<sub>2</sub> mixtures in confined spaces are not correct.

A comparison of the critical tube diameter of stoichiometric air/hydrogen mixtures ( $d_c = 20$  cm) with that of stoichiometric air/acetylene mixtures ( $d_c = 12$  cm) indicated that hydrogen is slightly less sensitive than acetylene [1034]. The relatively slow increase in  $d_c$  for H<sub>2</sub>-rich mixtures (as compared to lean mixtures) indicated that fuel-rich mixtures are more hazardous from the detonation point of view than fuel-lean mixtures. Detonability limit criteria for different boundary conditions were based on the cell size of the mixture. For fully confined detonations in tubes, limits were set by the onset of single-headed spin.

The rich and lean detonation limits of air/hydrogen mixtures are dependent on critical dimensions of the detonation channel. Extrapolation of laboratory scale air/hydrogen detonations, verified by some large-scale detonations, increased confidence for further extrapolation to the very large dimensions associated with nuclear reactor containment buildings where hydrogen may accumulate during reactor meltdown. Laboratory-scale experiments were complemented with large-scale experiments [1035–1037]. Both rich and lean air/hydrogen mixtures were confined in thin-wall (100  $\mu$ m) transparent polyethylene envelopes to provide minimum lateral confinement. The diameter of the envelopes ranged from 0.75 m to about 2 m, depending upon the mixture under study. For the critical tube diameter experiments, the polyethylene tube was attached to a steel tube which was generally smaller than the polyethylene tube. High explosive was used to launch a detonation in the steel tube, the emergent detonation wave then propagated into a larger diameter plastic envelope.

Flame acceleration studies of deflagrating hydrogen/air mixtures were carried out in free and partially confined homogeneous clouds [1038]. The experiments in an unconfined hemispherical configuration showed a distinct dependence of the flame velocity on the cloud size which did not exceed, however, an upper limiting value. The experiments under partially confined conditions without additional turbulence indi-

cated that the flame velocity and consequently the pressure field was governed by the hemispherical flame front initially formed, i.e. the flame velocity was not affected by the partial confinement. To increase the turbulence effects, further experiments were carried out with a fan and with jet ignition. In the case of fan-induced turbulence the flame velocity was strongly influenced by the fan speed. At a certain fan capacity the transition of a deflagration into a detonation was observed. With jet ignition produced by venting an explosion chamber into the partially confined cloud the transition occurred even with hydrogen concentrations in air as low as 22 vol.-%. Turbulence models showed that high damaging overpressures or the transition from a deflagration into a detonation are only generated by strong turbulences as a consequence of flow and/or obstacles.

Large-scale experiments have indicated that scale and geometric effects can strongly influence both the ability of an air/hydrogen mixture to propagate or sustain a detonation, and the probability that a deflagration will undergo a transition to detonation [1039]. The data showed that many past concepts concerning detonations, which were derived from small-scale experiments, should be revised. In particular, the occurrence of detonations may not be as unlikely as previously considered, especially in large-scale industrial environments in which obstacles are present.

Partial confinement may aid in the transition of burning hydrogen from deflagration to detonation. A “lane” is a long partial confinement of air/hydrogen mixtures, confined at the bottom and on two sides, but open to the top [1040].

Several different large-scale deflagration and detonation experiments of hydrogen and air mixtures were performed measuring flame-front time of arrival using ionization probes, blast pressure, heat flux, high-speed video, standard video and infrared video [943]. The large-scale open-space tests used a hemispherical facility that confined the mixture within a thin plastic tent that was cut prior to initiation of a deflagration. Initial homogeneous hydrogen concentrations varied from 15 to 30%. All tests were ignited at the bottom center of the facility using either a spark or, in one case, a small quantity of high explosive to generate a detonation. Spark-initiated deflagration tests were performed in a 1/5-scale tunnel using homogeneous hydrogen mixtures to compare against similar tests performed in the open space. Several experiments performed in the 1/5-scale tunnel released 0.1 and 2.2 kg of hydrogen into the tunnel with and without ventilation to represent, respectively, a release from a fuel cell vehicle or the storage cylinder on a hydrogen transport. A test was performed to investigate any enhancement of the deflagration due to partial confinement produced by a narrow gap between aluminum plates.

## **7.12.6 Gaseous Oxygen/Hydrogen Detonations**

### **7.12.6.1 Undiluted Gaseous Oxygen/Hydrogen Detonations**

Within the flammable range, mixtures of gaseous hydrogen with undiluted oxygen instead of air will always detonate, regardless of the mode of initiation and the de-

gree of confinement. While the flammable range of hydrogen in dry air is “only” 4.1–74.8 vol.-%  $H_2$ , the flammable and detonable range of hydrogen in oxygen is much wider, 4.1–94.0 vol.-%  $H_2$  [1015, 1041].

Detonation velocities were measured in mixtures of oxygen and hydrogen containing 25–75 mol-% hydrogen at initial temperatures from 160 to 580 K and initial pressures from 50.5 to 202 kPa (0.5–2 atm) [1042]. The measurements were made in a number of tubes of different diameter to permit extrapolation to a tube of infinite diameter. Theoretical detonation characteristics were computed for the same range of conditions. The measured and computed velocities were in good agreement except in rich mixtures and at subatmospheric pressures. Schlieren photographs revealed that the detonation wave front is very thin for a stoichiometric mixture but degenerated to a complicated zone of interacting shock waves and turbulent combustion as the percentage of hydrogen was reduced. The detonation velocity depended only slightly on initial temperature and pressure. The computed pressures behind the detonation and reflected waves were roughly proportional to the initial pressure and to the reciprocal of the initial temperature.

Detonation velocities of oxygen/hydrogen mixtures were measured for initial pressures from 99 kPa to 6.89 MPa (14.4–1000 psia) and compositions from 40 to 80 mol-% dihydrogen [1043]. Detonation and impact characteristics were computed for essentially the same range of conditions by the use of the elementary theory of detonation. Equilibrium compositions of oxygen/hydrogen mixtures at pressures from 1 to 202 MPa (10–2000 atm) and temperatures from 3000 to 5000 K were included in the computations. The effect of non-ideal thermodynamic properties on the computed detonation velocities must be considered.

Composition, temperature, pressure and density behind a stable detonation wave and its propagation rate have been calculated for 7 oxygen/hydrogen mixtures at 1, 5, 25, and 100 atm initial pressure, and at an initial temperature of 313 or 473 K (40 or 200 °C) [1044–1046]. According to these calculations the detonation velocities of oxygen/hydrogen mixtures increase with increasing initial pressure but decrease slightly when the initial temperature is raised from 313 to 473 K (40 to 200 °C). The calculated detonation velocities agreed with values determined experimentally.

The transition from deflagration to detonation occurs when the pre-flame shock becomes strong enough to cause the mixture to explode. The limits of detonability can be predicted if one knows:

1. The chemical-kinetics condition for branched-chain explosion of hydrogen in terms of temperature, pressure and mixture composition.
2. Standard shock-wave equations for a given mixture, the temperature and pressure of the shocked gas in terms of shock strength.
3. The explosion condition in terms of shock strength and mixture composition.

It will be found on the basis of conservation of energy that some mixtures, on burning, can support a shock of the critical strength, whereas others cannot. That delineates the limits of detonability [1047].

The detonability of gaseous oxygen/hydrogen mixtures contained in 61-cm and 91-cm (2-ft and 3-ft) diameter cylindrical vessels, 6.08 and 12.16 m long (20 and 40 ft long), was investigated for initial pressures ranging from 101 kPa to 13.3 Pa (760–0.1 mm Hg) and initial temperatures of 155, 200, 294, and 366 K (–180, –100, +70, and +200 °F) [1048, 1049]. Both strong igniters, comprised of approximately 70 grains of PETN, and weak sources of ignition, such as spark discharge, were used. Tests with PETN, which produced a strong initiating wave, indicated that detonation cannot be supported below an initial pressure of 10 mm Hg. In general, measured steady wave velocities were lower and pressures higher, than the corresponding theoretical Chapman-Jouguet values, the differences becoming more pronounced at lower initial pressures and temperatures. The weak igniter tests provided information on the development of detonation. Observations of initial flame acceleration were explained on the basis of a theory in previous studies in small-scale equipment, demonstrating its validity regardless of the size of the apparatus.

A study was performed on the detonation properties of cryogenic mixtures of gaseous hydrogen and oxygen at 100 K initial temperature and various initial pressures and equivalence ratios [1050]. Measured detonation pressures and velocities agreed quite well with the computed C-J values based on the ideal gas equation of state. Numerical computations of idealized, steady-state, one-dimensional structures with detailed chemical reaction kinetics were used to evaluate the reaction zone thickness and to estimate cell size, critical tube diameter and critical initiation energy. Predictions of critical tube diameter using calculated reaction zone thickness agreed reasonably well with experimental data. The kinetic modeling indicated that the initial pressure had a much smaller effect on reaction zone length at low initial temperatures (50–100 K) than at room temperature (300 K). This was due to a shift in the reaction mechanism as initial density (and, therefore, final pressure) increased with decreasing initial temperature at a fixed initial pressure.

#### 7.12.6.2 Gaseous Oxygen/Hydrogen Detonations with Diluents

Numerous experiments have been conducted with detonations of oxygen/hydrogen mixtures with inert diluents other than nitrogen or with oxygen : nitrogen ratios in the oxidizer other than 21 : 79. The objective was to slow down the reaction so it could be safely studied without destroying the apparatus. Other studies compared the well-known nitrogen diluent in air to the effect of other inert diluent gases on detonation limits and detonation velocities.

A test apparatus was designed to simulate the space around the shaft that connects the turbine and the turbopumps in a liquid hydrogen rocket engine [1051]. Hydrogen leakage past the rotary seals in a hydrogen pump is difficult to avoid. This space is typically purged with helium to reduce the risk of fires or explosions. The flammabil-

ity limits for a gap size of 5.3 mm (0.21 in.) were 8.1 vol.-%  $H_2$  LFL and 90.6 vol.-%  $H_2$  for the UFL in oxygen. The flammability limits for the apparatus without an inner cylinder were 5.8 vol.-%  $H_2$  LFL and 91.2 vol.-%  $H_2$  UFL. Additional measurements were made with different gap widths of 2.5 and 0.6 mm (0.1 and 0.025 in.) [1052].

The limiting (minimum) concentrations of hydrogen in oxygen, in the presence of added helium, at elevated temperatures and pressures were determined in a 5-L explosion vessel [1053]. The limiting concentrations of hydrogen in oxygen and helium at different initial pressures and temperatures, and the influence of ignition energy and initial temperature on the limiting concentration of hydrogen in oxygen and helium were measured. The variation of ignition energy was found to have a significant effect on the limiting concentration of hydrogen in oxygen and helium at lower initial temperatures; however, when the ignition energy was above 32 mJ, the limiting hydrogen concentration remained almost unchanged as the initial temperature was increased from 294 to 363 K (21 to 90 °C). The limiting explosive concentration of oxygen/hydrogen/helium mixtures decreased as the ignition energy increased when the initial temperature was lower. When the initial temperature was higher, the ignition energy had little effect on the limiting hydrogen concentration of oxygen/hydrogen/helium mixtures. When the initial temperature was set at 363 K (90 °C), the limiting hydrogen concentration remained almost unchanged with an increase in ignition energy. The limiting explosive concentration of hydrogen in the mixtures, at the initial temperature of 294 K (21 °C) and an ignition energy of 0.5 mJ, was 8.5 vol.-% and that of oxygen was 11.25 vol.-%.

Detonation limits in two stoichiometric  $O_2/H_2/Ar$  mixtures ( $O_2 + 2H_2 + 3Ar$  and  $O_2 + 2H_2$ ) were tested in three different diameter round tubes ( $D = 1.8, 4.6,$  and  $10.9$  mm) [1054]. The choice of the two mixtures represented those considered as “stable” with a regular cellular pattern and “unstable” with an irregular cellular pattern. Detonation velocity was measured by ionization probes spaced at regular intervals along the small tubes. Consistent with previous findings, the results showed that while well within the limits the detonation wave in hydrogen mixtures propagated at a steady velocity close to the theoretical C-J value. With decreasing initial pressure, the velocity deficit increased. It was found that the detonation velocity decreased with decreasing tube diameter, which is a result of the wall boundary layer effect being more prominent for smaller tubes. At the limiting pressure, the steady velocity decrease for both tested mixtures in three different diameter tubes was about 15–18%. Velocity deficits were estimated theoretically using the Fay model. For the mixture of  $O_2 + 2H_2 + 3Ar$ , good agreement was found between the theoretical prediction and the experimental result of detonation velocity. For the mixture of  $O_2 + 2H_2$ , however, the theoretical prediction deviated from the experimental measurement. This observation suggested that, apart from losses due to the flow divergence caused by the boundary layer effect, instabilities are also significant for the detonation propagation and failure in an  $O_2 + 2H_2$  mixture. At the limits of propagation, the value of  $D/\lambda$  was found to agree with that for the onset of single-headed spin detonation.

It was concluded that the single-headed spin criterion can be used for defining the detonation limits for hydrogen mixtures. See also [1029, 1030].

### 7.12.6.3 Study of Gaseous Oxygen/Hydrogen Detonations in Shock Tubes

Oxygen/hydrogen gas mixtures are often used in the driver (donor) section of shock tubes to reproducibly produce shock waves of known strength and measure their effects on other gas mixtures [1055].

The shock strength required to ignite stoichiometric oxygen/hydrogen mixtures corresponds to an ignition temperature that is in agreement with explosion limit data measured in glass bulbs [1056]. This is surprising, because the existence of explosion limits implies a steady state involving diffusion of reacting species to and from, and reaction at the walls of the reaction vessel. Such a condition is not expected to exist in a shock tube experiment. Measurements on several hydrogen mixtures near the composition limits of detonation showed that the agreement is fortuitous and is not a general feature of shock wave ignition. They also showed that there is no apparent relation between ignition and detonation limits. There are chemical factors that determine the limits, and it was concluded that the chain branching reaction plays a controlling role.

Shock-induced ignition and combustion of hydrogen was examined by stabilizing a flame behind the normal shock wave of a Mach-reflected shock pattern generated in a high temperature airstream of Mach number 1.91 [1057]. The stagnation temperature was varied from 1000 to 1400K to identify its effects on the shock configurations and the flame induction length. It was found that the exothermic chemical reaction behind the normal shock wave caused it to increase in size and to move upstream. The flow expansion behind the normal shock wave had quenched the downstream portion of the induced flame but a quasi one-dimensional reactive flow calculation revealed that effect of the expansion on the induction length was not as important as that of chemical kinetics.

The detonation in  $O_2/H_2/He/Ar$  mixtures at elevated initial pressures was investigated in an initiation tube for a detonation driver with an exploding wire as the ignition source [1058]. In most experiments the detonation wave was formed by a DDT process in which a reactive shock wave accelerated behind the leading shock wave and eventually made a transition to the onset of detonation. The onset position was found to be at the leading shock wave or behind it. Only in very sensitive mixtures at high initial pressures was the direct initiation of detonation observed. The influence of ignition energy, initial pressure, and composition on the detonation induction distance was determined. The results showed that the detonation induction distance increased with the decrease of ignition energy and initial pressure and with the increase of the mol fraction of helium or argon. With the same mol fraction, argon increased the induction distance more than helium. The DDT upper and lower limits of hydrogen in  $O_2/H_2$  mixtures were in the ranges from 36 to 40% and from 78 to 82%, respectively, and the upper limits for helium and argon in stoichiometric  $O_2/H_2$  mixtures were 40

and 36%, respectively. High pressure peaks generated by the DDT process were measured, especially in mixtures near the DDT limits. Such peak pressures can be up to 6 times higher than the C-J pressures.

The ignition of oxygen/hydrogen mixtures by detonation waves at 0.1–0.5 MPa and mixture ratios of 1.6–9.4 at room temperature was measured in a shock tube [1059]. The results showed that pressures above 1 MPa and temperatures over 1573 K (1300 °C) could be produced from lower gas pressures by the detonation wave ignition technique, and the variation in ignition delay time from run to run was less than 0.3 ms.

The temporal variation of  $\bullet\text{OH}$  chemiluminescence in hydrogen oxidation chemistry has been studied in a shock tube behind reflected shock waves at temperatures of 1400–3300 K and at a pressure of 1 bar [1060]. The aim of that work was to obtain a validated reaction scheme to describe  $\bullet\text{OH}$  formation in the  $\text{O}_2/\text{H}_2$  system. Temporal  $\bullet\text{OH}$  emission profiles and ignition delay times for lean and stoichiometric  $\text{O}_2/\text{H}_2$  mixtures diluted in 97–98% argon were obtained from the shock tube experiments. The key reaction considered was

The temperature dependence of the measured peak  $\bullet\text{OH}$  emission from the shock tube and the peak  $\bullet\text{OH}$  concentration from a homogeneous closed reactor model were compared. Based on these results a reaction rate coefficient of

$$k_1 = (1.5 \pm 0.4) \times 10^{13} \exp(-25 \text{ kJ mol}^{-1}/RT) \text{ cm}^6 \text{ mol}^{-2} \text{ s}^{-1}$$

was found for the forward reaction (R1) which was slightly higher than the rate coefficient reported by others.

Ignition delay times of  $\text{O}_2/\text{H}_2$  mixtures highly diluted with Ar and doped with varying amounts of  $\text{N}_2\text{O}$  (100, 400, 1600, 3200 ppm) were measured in a shock tube behind reflected shock waves over a wide range of temperatures (940–1675 K) and pressures (1.6, 13, and 32 atm) [1061]. Ignition delay times were decreased when  $\text{N}_2\text{O}$  was added to the mixture only for the higher nitrous oxide concentrations and decreases were proportional to the amount of  $\text{N}_2\text{O}$  added. A chemical kinetics model was developed using kinetic mechanisms from the literature. This model predicted and matched the experimental data obtained during this study and from the literature. The chemical analysis using this model showed that the decrease in the ignition delay time was mainly due to the reaction  $\text{N}_2\text{O} + \text{M} \rightarrow \text{N}_2 + \text{O}\bullet + \text{M}$  which provides  $\bullet\text{O}$  atoms to strengthen the channel  $\text{O}\bullet + \text{H}_2 \rightarrow \bullet\text{OH} + \text{H}\bullet$ .

### 7.12.7 Deflagration-to-Detonation Transitions

Because very powerful ignition sources such as solid explosives are usually required to initiate unconfined air/hydrogen detonations, most accident scenarios assign a very low probability to the detonation mode (as opposed to deflagration mode) in accidental air/hydrogen explosions; however, detonations cannot be completely ruled out,

since depending on geometry, a flame can accelerate to a sufficiently high speed and transit to detonation. An explosive mixture at given initial and boundary conditions is expected to undergo transition from deflagration to detonation (DDT) if the following conditions are satisfied: **(1)** the mixture composition must be within the detonability limits, and **(2)** powerful acceleration mechanisms such as turbulence generated by obstacles and adequate boundary conditions (confinement) must be present. Therefore, the transition event involves detonability limits, flame acceleration mechanisms, and the mechanisms responsible for the onset of detonation itself.

Flame acceleration and DDT transitions can occur in straight tubes but are more likely to occur when the combustion front encounters obstacles in its travel which cause turbulence and hot spots. Whereas for confined mixtures, DDT may result from flame acceleration due to turbulence generated by obstacles, large-scale experiments without obstacles indicated that turbulent jet mixing is the mechanism responsible for DDT in unconfined mixtures.

Air/hydrogen combustion can start as a detonation, or it can start as a deflagration and then transition to a detonation after the flame has traveled for some distance [523]. The composition range in which a detonation can take place is narrower than that for deflagration. The commonly quoted range for detonation in an air/hydrogen mixture is from 18.3 to 59 vol.-% hydrogen; however, with higher energy ignition/initiation sources, the limits can be extended. The factors that influence whether air/hydrogen combustion will occur as a detonation rather than as a deflagration include the hydrogen percentage, the strength of the initiator, complete or partial confinement of the reaction, and the presence of structures that can induce turbulence in the flame front. An energetic source of initiation is required for combustion to start as a detonation. A mechanism to accelerate the flame velocity is necessary for a deflagration to transition to detonation. Factors that favor this transition include the composition being within the detonation range, a degree of confinement, and anything that can induce turbulence in the flame front as it travels through the combustible mixture. The latter tends to stretch out the flame front and increase its velocity [1062, 1063]. A special case occurs when a deflagration combusts and propagates into a “dead-headed” volume. This can lead to exceptionally high overpressures. Under such circumstances (also described as pressure-piling), the unburned gases in the worst case can pressurize to the dynamic pressure produced by the accelerated flame [1064]. Under these conditions, should DDT ensue, the worst-case result can be an overpressure that is characterized by the multiplicative factors of both deflagration and detonation, far beyond the initial pressure within the system.

Dynamic detonation and DDT parameters of air/hydrogen explosions were reviewed [1024]. These parameters included the characteristic chemical length scale, such as the detonation cell width, associated with the three-dimensional cellular structure of detonation waves, critical transmission conditions of confined detonations into unconfined environments, critical initiation energy for unconfined detonations, detonability limits, and critical conditions for DDT. The detonation

cell width, which depends on hydrogen and diluent concentrations, pressure and temperature, is an important parameter in the prediction of critical geometry-dependent conditions for the transmission of confined detonations into unconfined environments and the critical energies for the direct initiation of unconfined detonations. Detonability limits depend on both initial and boundary conditions. The criteria for DDT are different for smooth-walled tubes and tubes with trip ledges (obstacles). The report was intended to examine all aspects of detonative combustion that are commonly studied and are of practical interest. These included problems of initiation, transition, transmission, and detonability limits.

The equilibrium detonation parameters (i.e., detonation velocity, pressure, density and temperature ratios, and equilibrium composition of the reaction products) are adequately predicted by the classical C-J theory, which models gaseous detonation waves as one-dimensional, steady combustion waves; however, the C-J theory, which is essentially an equilibrium calculation, cannot predict the non-equilibrium or dynamic detonation parameters which are related to the chemical reaction rates, i.e., to the structure of the detonation wave.

Accidental ignition in flammable air/hydrogen/diluent mixtures will normally lead to a deflagration wave (slow flame). A freely propagating flame strongly influences the flow conditions ahead of it. Particular conditions can accelerate this flame and cause a transition from deflagration to a detonation wave (rapid flame), with its spatially non-uniform and very high blast pressures [1065]. The differences between deflagration and detonation of air/H<sub>2</sub> mixtures were outlined, and the various flame acceleration mechanisms were reviewed. The DDT was described as a two-step process, a local explosion followed by an amplification of the resulting blast wave into a detonation wave. This was based on the occurrence of a local explosion in hot spots generated by the focusing of shock waves existing ahead of a fast flame, or in high-reactivity centers generated by turbulence-induced rapid mixing of flame and unburnt gas, and the resulting local quenching of the flame. There are only few qualitative criteria available for assessing the likelihood of transition to detonation under a set of given starting conditions. A goal of the study was to develop a quantitative methodology for assessing this likelihood.

The emergency venting of a gaseous deflagration is widely used to prevent severe consequences of a confined explosion. Processes of vented deflagrations have been studied extensively and a substantial amount of experimental data has been analyzed. It has been found that venting, in some cases, can result in strong explosions [1066]. This may be caused by flame instabilities, which give rise to a flame area increase, and the generation of high peak overpressures. Onset of detonations has been observed in the course of hydrogen-air deflagration, due to sudden venting. Although the aim of the tests initially was not to investigate the effect of venting on gaseous explosions, this effect appeared to be defining the explosion mode, based on unconfined turbulent jet initiation experiments. Test variables were hydrogen concentration, jet orifice diameter, and size of the enclosure. Measurement equipment included pressure trans-

ducers, photodiodes, and two high-speed cameras (2500 frames/s). Contact gauges gave the times of jet membrane rupture and of panels destruction.

Large-scale experiments on turbulent flame propagation and transition to detonation in a confined volume of lean hydrogen-air mixtures were conducted in a strong concrete enclosure of  $480\text{ m}^3$ , and  $69.9\text{ m}$  length with a straight channel ( $34.6\text{ m}$  length,  $2.3\text{ m}$  height,  $2.5\text{ m}$  width) with or without obstacles, a canyon ( $10.55 \times 6.3 \times 2.5\text{ m}$ ), and a final channel to study the effect of hydrogen concentration (9.8–14 vol.-%) on turbulent flame propagation and transition to detonation [1067]. Ignition was with a weak electric spark at the beginning of the first channel. A minimum of 12.5 vol.-% of hydrogen was necessary for transition to detonation. This is a much less sensitive mixture than those in which the onset of spontaneous detonation has previously been observed (minimum of 15 vol.-% of hydrogen in air).

The High-Temperature Combustion Facility at Brookhaven Natl. Lab. was used to conduct DDT experiments [950, 951]. Periodic orifice plates were installed inside the entire length of the detonation tube in order to promote turbulence and flame acceleration. The orifice plates were  $27.3\text{ cm}$  outer diameter, which is equivalent to the inner diameter of the tube, and  $20.6\text{ cm}$  inner diameter. The detonation tube was  $21.3\text{ m}$  long, and the spacing of the orifice plates was one tube diameter. A standard automobile diesel engine glow plug was used to ignite the test mixture at one end of the tube. Hydrogen-air-steam mixtures were tested at a range of temperatures up to  $650\text{ K}$  and at an initial pressure of  $0.1\text{ MPa}$ . In most cases, the limiting hydrogen mol fraction which resulted in DDT corresponded to the mixture whose detonation cell size,  $\lambda$ , was equal to the inner diameter of the orifice plate,  $d$  (e.g.,  $d/\lambda = 1$ ). The only exception was in the dry hydrogen-air mixtures at  $650\text{ K}$  where the DDT limit was 11 vol.-% hydrogen, corresponding to a value of  $d/\lambda$  equal to 5.5. For a 10.5 vol.-% hydrogen mixture at  $650\text{ K}$ , the flame accelerated to a maximum velocity of about  $120\text{ m/s}$  and then decelerated to below  $2\text{ m/s}$ . It was observed that the distance required for the flame to accelerate to the point of detonation initiation, referred to as the run-up distance, was a function of both the hydrogen mol fraction and the gas mixture initial temperature. Decreasing the hydrogen mol fraction or increasing the initial mixture temperature resulted in longer run-up distances.

Critical conditions for onset of detonations were compared at **(1)** two significantly different scales, **(2)** for a range of air/ $\text{H}_2$  mixtures diluted with  $\text{CO}_2$  or  $\text{H}_2\text{O}$ , and **(3)** for two types of geometry: one a long, obstructed channel and the other a room with a relatively small aspect ratio [1068]. For the range of scales, mixtures and initial conditions tested, the detonation cell size  $\lambda$  was shown to be a reliable scaling parameter for characterization of detonation onset conditions. An experimental correlation was suggested for the critical detonation onset conditions. This correlation was based on a wide variety of available experimental data on DDT in mixtures of hydrogen and hydrocarbon fuels with air and on the use of detonation cell size  $\lambda$  as a scaling parameter characterizing the mixture.

Turbulent flame propagation in obstructed channels was measured over a wide range of air/H<sub>2</sub> and air/H<sub>2</sub>/steam. From lean to rich mixtures at normal and elevated initial temperatures. From 298 to 650 K and pressures. From 1 to 3 bar and stoichiometric O<sub>2</sub>/H<sub>2</sub> mixtures diluted with N<sub>2</sub>, Ar, He, and CO<sub>2</sub> at normal initial conditions [1069]. It was shown that basic flame parameters, such as mixture expansion ratio  $\sigma$ , Zeldovich number  $\beta$ , and Lewis number Le, can be used to estimate *a priori* a potential for effective flame acceleration for a given mixture. Critical conditions for effective flame acceleration were suggested in the form of correlations of critical expansion ratio  $\sigma^*$  versus dimensionless effective activation energy. On this basis, limits for effective flame acceleration for hydrogen combustibles can be estimated with only modes uncertainties in critical  $\sigma^*$  values.

Flame acceleration and DDT in obstructed channels was modeled using 2-D reactive Navier-Stokes numerical simulations [1070]. The energy release rate for stoichiometric hydrogen-air mixtures was modeled by one-step Arrhenius kinetics. Channels with symmetrical and staggered obstacle configurations showed two main effects of obstacle spacing (S). First, more obstacles per unit length created more perturbations that increased the flame surface area more quickly, and therefore the flame speed grew faster. Second, DDT occurred more easily when the obstacle spacing was large enough for Mach stems to form. These two effects were responsible for three different regimes of flame acceleration and DDT observed in these simulations: **(1)** detonation was ignited when a Mach stem by the diffracting shock reflecting from the bottom wall collided with an obstacle, **(2)** Mach stems did not form, and the detonation was not ignited, and **(3)** stems did not form, but the leading shock became strong enough to ignite a detonation by a direct collision with the top part of an obstacle. For staggered obstacle configurations, resonance phenomena significantly reduced the DDT time when  $S/2$  was comparable to the channel width in regime **(1)**. Simulations also showed that phenomena responsible for DDT are the same for obstructed channels and 2D arrays of obstacles, even though final detonation ignition may be different. A detailed overview of flame acceleration and transition to detonation in ducts is available in [951].

The hazardous potential of air/hydrogen mixtures has intensively been studied assuming a perfectly homogeneous mixture of oxidant and fuel; however, comprehensive risk assessment studies have shown that an inhomogeneous mixture with a vertical concentration gradient is much more likely to be generated in a real accident scenario. From a safety point of view, an open question was whether established criteria such as the  $7\lambda$  criterion for the determination of the DDT limits can be applied to inhomogeneous mixtures as well. For the experimental investigation of DDT in such mixtures an injection mechanism has been developed that produced vertical fuel concentration gradients inside a horizontal channel with large aspect ratio [1071]. The channel was equipped with obstacles to enhance flame acceleration. Photodiodes and pressure transducers measured flame and shock arrival times. Schlieren measurements were conducted to track gas mixing behind the obstacles and to track the for-

mation of the detonation wave front. In the experimental study, the fuel content, the strength of concentration gradient, the blockage ratio, and the spacing of the obstacles inside the channel were varied. The maximum flame velocity observed in each experiment was compared with the velocities obtained from one-dimensional theory. A DDT leads to a steep velocity rise from the sound speed of the combustion products to the Chapman-Jouguet velocity of the mixture and generated a considerable increase in peak pressure.

A numerical approach to simulate flame acceleration and DDT in air/hydrogen mixtures and two different approaches to detonation modelling provided predictions in identical scenarios which were then compared [1072]. The DDT model solved fully compressible, multi-dimensional, transient, reactive Navier-Stokes equations with a chemical reaction mechanism for different stages of flame propagation and acceleration from a laminar flame to a highly turbulent flame and subsequent transition from deflagration to detonation. The model has been used to simulate flame acceleration and DDT in a 2-D symmetrical rectangular channel with 0.04 m height and 1 m length which is filled with obstacles. Comparisons were made between the predictions using a 21-step detailed chemistry or a single-step reaction mechanism. The effect of initial temperature on the run-up distances to DDT has been investigated. Another detonation equation solver was developed based on the solution of reactive Euler equations while the other solver took a simpler approach based on C-J model and the programmed C-J burn method. Comparison has shown that the relatively simple C-J burn approach is unable to capture some very important features of detonation when there are obstacles present in the cloud.

A model for the CFD simulation of air/hydrogen explosions (including DDT) in large volumes was validated by means of the largest ever conducted indoor DDT experiments in the RUT facility operated by Kurchatov Institute in Russia [1073]. A combination of models was developed with a particular emphasis on the influence of flame instabilities, especially of a thermal-diffusive nature, which are crucial for combustion of very lean mixtures. Good agreement was achieved in terms of flame acceleration. The quality of DDT predictions itself depended on the underlying mechanism. Whereas DDT by shock-focusing was successfully simulated on under-resolved meshes, DDT by local explosions in the vicinity of the turbulent flame brush remained a challenge. Adaptive mesh refinement therefore emerged as a key technique to resolve more of the essential phenomena at reasonable computational costs. A generic example case demonstrated the influence of mixture inhomogeneity, which can promote flame acceleration and ultimately DDT.

Air/H<sub>2</sub> and O<sub>2</sub>/H<sub>2</sub> flame propagation across a single obstacle in a closed channel has been studied by means of simultaneous single image planar laser-induced fluorescence (PLIF) and high-speed schlieren visualization [1074]. The test mixtures were stoichiometric O<sub>2</sub>/H<sub>2</sub> at an initial pressure of 8 kPa and lean air/H<sub>2</sub> ( $\varphi = 0.5$ ) at an initial pressure of 100 kPa. The OH-PLIF technique overcomes the problem of line-of-sight integration associated with schlieren visualization and thus enables the investigation of

flame topology. For  $O_2/H_2$ , a smooth (laminar) flame front was observed upstream of the obstacle. Downstream, the flame interacted with vortices being shed off the obstacle corners and appeared wrinkled in the obstacle recirculation zones.

A CFD explosion modeling for lean air/hydrogen mixtures with 6–19 vol.-%  $H_2$  on under-resolved grids can now be validated with data obtained from an entirely enclosed laboratory scale explosion channel at  $p = 1 \text{ atm}$  and  $T = 293 \text{ K}$  [1075]. Two time-resolved optical measurement techniques were applied simultaneously: (1) 10 kHz shadowgraphy captured line-of-sight integrated macroscopic flame propagation and (2) 20 kHz OH-PLIF (planar laser-induced fluorescence of the OH radical) resolved microscopic flame topology without line-of-sight integration. A detailed time-resolved quantification of flame topology based on OH-PLIF images revealed the expected enlargement of flame surface area by instabilities on microscopic level and a strong dependence on mixture composition.

In the real world, combustible air/hydrogen mixtures causing catastrophic damage are usually inhomogeneous and subject to both vertical and horizontal concentration gradients. There was still very limited understanding of the explosion characteristics in such situations. A study aimed to investigate DDT in such inhomogeneous mixtures [1076]. Two sample cases in a horizontal obstructed channel with 30 and 60% blockage ratios filled with air/hydrogen mixtures with vertical concentration gradients were numerically modeled. These cases were experimentally investigated and hence some experimental measurements are available for model validation. The numerical results were in good agreement with the experiments. The predictions showed that the overpressure at the DDT transition stage is higher in the non-uniform mixtures than in homogeneous mixtures under similar conditions. It was also found that increasing the blockage ratio from 30 to 60% resulted in faster flame propagation and lower propensity to DDT.

The possibility of a laminar flame in a stoichiometric  $H_2/O_2$  mixture accelerating along a cylindrical tube, closed at one end, and transitioning from a deflagration to detonation was analyzed [1077]. It was predicted that the pressure and temperature ratios at the ensuing shock wave increase as do laminar burning velocities, while autoignition delay times decrease. Combined with appreciable elongation of the flame, these enhance the strength of the shock. The conditions necessary for delay times of 0.05, 0.1, 1.0, and 5.0 ms, at an unburned mixture critical Reynolds number of 2300, were computed for different tube diameters. Probable consequences of the different delay times and hot spot reactivity gradients, including detonation must be considered. The probability of a purely laminar propagation leading to a detonation is marginal. Only when the initial temperature is raised to 375 K, do purely laminar detonations become possible in tubes of between about 0.5 and 1.35 mm diameter.

#### 7.12.7.1 Detonation Induction Distance in Air/Hydrogen Mixtures

The detonation induction distance is the distance required for a DDT in a detonable fuel-air mixture. This distance is usually experimentally determined in a long cylin-

dricial tube with a spark or hot wire ignitor on one end of the tube. The tube is instrumented along its length to sense the velocity of the flame front as it propagates through the detonable mixture of gases. The distance from the ignitor to the axial position in the tube where the flame front first attains the detonation velocity is defined as the induction distance. This distance is dependent upon the combustible mixture constituents, the pressure, temperature, and concentration of the gaseous mixture, the enclosure geometry and strength of the ignition source. A deflagration is a low order explosion resulting from subsonic flame speed, relative to the unburned gas. It is conventionally defined as a propagating reaction in which the energy transfer from the reaction zone to the unreacted zone is achieved through ordinary rate-limiting transport processes such as radiation and convection heat transfer and mass transfer. A detonation is a high-order explosion resulting from supersonic flame speed, relative to the unburned gas. It may be defined as a propagating reaction in which energy is transferred from the reaction zone to the unreacted zone on a reactive shock wave [1033, 1078]. Detonations may propagate in flowing oxygen/hydrogen mixtures, but always faster than the unburnt gases can flow [1079].

In order to study the combustion of unconfined samples, combustion tests with air/gaseous hydrogen mixtures were conducted in balloons of 1.5 and 2.4 m diameter with contents of 2380 and 11320 L of mixed gas. Initiation was through detonators, flames, glowing wires or sparks [497]. The first tests showed that in a 1.5-m balloon with near-stoichiometric mixtures it will not come to a three-dimensional shock wave if the initiation does not have enough energy. In order to achieve detonations in 100% of the cases, a booster charge of 2 g PETN was required. A detonator that contains only 0.5 g primary explosive would cause a detonation in only 5% of the several tests conducted. Flames, hot wires, and sparks caused the mixtures to burn peacefully without measurable pressure spikes. Subsequent tests were all conducted with a 2-g booster and the effect of mixture ratio on detonable limits was bracketed. The highest detonation pressure spikes were obtained with mixtures containing 30–40 mol-% hydrogen. The explosive range in a 1.5-m balloon was from 20 to 50 mol-%  $H_2$ . This range is very similar to the range observed in confined samples in tubes (18–59 mol-%  $H_2$ ). The scale effect was studied by comparing results with larger 2.4-m balloons to those with the 1.5-m balloons. The question was if the longer pathway will facilitate a transition from combustion to detonation and to determine the critical diameter for unconfined explosions. Similar to earlier results with the 1.5 m balloon, detonations were only observed with the 2-g booster and occasionally with the detonator by itself. The ignition by spark caused only a smooth combustion without explosion. The tests showed that unconfined air/hydrogen mixtures can be made to detonate only by using a strong booster charge as the initiation source. Because it is unlikely that a detonator or a booster charge will detonate accidentally in the vicinity of hydrogen spills, the danger of air/hydrogen explosions as a result of hydrogen spills is relatively low.

### 7.12.7.2 Detonation Induction Distance in Air/Hydrogen and Oxygen/Hydrogen Mixtures

The detonation induction distances in oxygen/hydrogen mixtures depend on the mode of initiation and the extent of confinement [1080, 1081]. The detonation induction distance is also called the run-up distance.

While extensive studies have been conducted examining the formation of detonation waves in various combustible gaseous mixtures under static conditions, there was very little experimental work on propagation of detonations in simple flowing systems. Experiments on the DDT of a flowing air/hydrogen stream were carried out to see the effects of tube diameter, equivalence ratio and flow types on flame propagation in a pre-mixed and non-premixed flow [1082]. Tube diameters used were 25, 50, and 100 mm. The pre-mixed experiments showed that the larger tube diameter provided a wider range in run-up distance, reduction of  $L_{DDT}/D$  (ratio of the run-up distance,  $L_{DDT}$  to tube diameter  $D$ ), and expansion of the detonable concentration limit by spreading the cell width. The result of the non-premixed experiments showed that similar values of the run-up distance to the pre-mixed experiments were obtained at an equivalence ratio of about 1.0; however, fluctuations of DDT occur near the DDT concentration limit. Under laminar flow conditions at a Reynolds number of less than 2300, the difference between the two systems could not be observed; however, when the Reynolds number increased towards turbulent conditions, the DDT run-up distance decreased compared to that of static flow conditions.

It was observed that the distance required for the flame in air/hydrogen mixtures to accelerate to the point of detonation initiation, referred to as the run-up distance, was a function of both the hydrogen mol fraction and the gas mixture initial temperature. Decreasing the hydrogen mol fraction or increasing the initial mixture temperature resulted in longer run-up distances [950, 951].

## 7.12.8 Overpressure from Air/Hydrogen Explosions

### 7.12.8.1 Overpressure from Unconfined Air/Hydrogen Explosions

The ignition of air/GH<sub>2</sub> mixtures usually results in ordinary deflagration. In general, without initiation sources that produce strong shock waves (such as high explosives or powerful electric arcs), flammable unconfined hydrogen mixtures ignited in the open do not produce significant overpressure.

Field explosion tests have been performed to obtain fundamental data concerning the explosion strength generated by a stoichiometric mixture of hydrogen and air [1083]. Hydrogen-air mixtures filled in a tent covered with thin plastic sheets were ignited by an electric spark to explode. The generated blast wave pressure was measured with piezoelectric pressure sensors. Deflagration tests with volumes of 9.4, 75, and 200 m<sup>3</sup> were carried out to investigate the scale effect (i.e. volume dependency) of peak overpressure and blast wave impulse. The measured data showed that peak overpressure and impulse exhibited different volume dependencies. Similar field ex-

plosion tests of three air/hydrogen mixtures with hydrogen contents of 21.0, 28.7, and 52.9 vol.-% were carried out in a volume of 31 m<sup>3</sup> [1084]. Each mixture was ignited by a booster charge of 0.1 kg of Composition C-4 explosive and guided to detonation. Peak pressures of blast waves caused by detonation were measured by piezoelectric pressure sensors. The measured peak overpressures and impulses were comparable in intensity to those of the TNT equivalent in lower heating value. The results showed that the strength of a blast wave generated by detonation of air/hydrogen mixtures is approximately the same as that of a TNT explosive.

A simple method for approximate evaluation of blast effects and safety distances for unconfined hydrogen explosions included models for flame speeds, hydrogen dispersion, blast overpressure parameters and blast damage criteria [1085]. An example of the application of this methodology for accidental hydrogen release in three hypothetical obstructed areas with different levels of congestion was presented. The severity of the blast effect of unconfined hydrogen explosions was shown to depend strongly on the level of congestion (confinement) for relatively small releases. Extremely large releases of hydrogen were predicted to be less sensitive to the congestion level.

Development tests were conducted to characterize unconfined air/hydrogen and oxygen/hydrogen blast characteristics [1086]. Most of the existing experiments for these types of explosions address contained explosions, like in shock tubes. Therefore, a Hydrogen Unconfined Combustion Test Apparatus was developed as a gaseous combustion test device for determining the relationships between overpressure, impulse and flame speed at various mixture ratios for unconfined reactions of oxygen/hydrogen and air/hydrogen. The system consisted of a central platform plumbed to inject and mix component gasses into an attached translucent bag or balloon with 340 or 1850 L while monitoring hydrogen concentration. All tests were ignited with a spark. Surrounding the platform were 9 blast pressure “Pencil” probes. Two high-speed cameras were used to observe flame speed within the combustion zone. The entire system was raised approx. 1.5 m (6 ft) off the ground to remove any ground reflection from the measurements. Overpressure and impulse data obtained from these tests were used to calibrate engineering analysis tools, CFD models and in the development of blast and fragment acceleration models.

A computational fluid dynamics simulation software was used to determine the potential of unconfined hydrogen in air to explode [1087]. The study included the analysis of parameters that can promote hydrogen vapor cloud explosions, e.g., initial pressure, time to ignition and leak height position. The study concluded that leaking high-pressure hydrogen has the potential to build up a large vapor cloud and may explode even without confinement when the leak source is close to the ground. The highest overpressure produced in the simulation was 0.71 bar gauge, which resulted from igniting a hydrogen gas cloud from a 207 bar hydrogen source leaking at 1 m height. The high overpressure suggested that hazard studies for hydrogen leaks near the ground should not assume a free flow jet release.

### 7.12.8.2 Overpressure from Confined and Vented Air/Hydrogen Explosions

Vented explosion tests using lean air/hydrogen mixtures with concentrations from 12 to 19 vol.-%  $H_2$  in a  $63.7\text{ m}^3$  chamber with a vent size of either  $2.7$  or  $5.4\text{ m}^2$  were focused on the effect of hydrogen concentration, ignition location, vent size, and obstacles on the overpressure development of a propagating flame in a vented enclosure [1088]. Deriving an equation for the dependence of the maximum pressure generated on the experimental parameters confirmed that the pressure maxima were caused by pressure transients controlled by the interplay of the maximum flame area, the burning velocity and the overpressure generated outside of the chamber by an external explosion.

A series of medium-scale experiments on vented hydrogen deflagration was carried out in a chamber of  $1 \times 1 \times 1\text{ m}$  size with different vent areas [1089]. The experimental program was divided in three series: **(1)** uniform air/hydrogen mixtures, **(2)** stratified air/hydrogen mixtures within the enclosure and **(3)** a layer deflagration of uniform mixture. Different uniform air/hydrogen mixtures from 7 to 18% hydrogen were tested with variable vent areas of  $0.01$ – $1.0\text{ m}^2$ . One test was done for a rich mixture with 50%  $H_2$ . Experiments with stratified air/hydrogen mixtures had about 4%  $H_2$  at the bottom and 10–25%  $H_2$  at the top of the enclosure.

Validated computational fluid dynamics (CFD) based methodologies for predicting propellant detonations and blast environments relevant to rocket propulsion test and launch facilities were developed [1090]. Verification and validation studies were conducted for hydrogen-fueled detonation phenomena such as shock-induced combustion, confined detonation waves, vapor cloud explosions, and DDT processes. The DDT validation cases included predicting flame acceleration mechanisms associated with turbulent flame-jets and flow-obstacles. The CFD methodology was applied to model a detonation event that occurred during liquid oxygen/gaseous hydrogen rocket diffuser testing at NASA Stennis Space Center.

Two thermochemical models have been derived for predicting the post-ignition state of hydrogen explosions in the containment vessel of a melting water-cooled nuclear reactor [1091]. The first model was based on internal energy balance while the second model used the concept of element potentials to minimize the free energy of the system with internal energy imposed as a constraint. Predictions from both the models were compared against published data over a wide range of mixture compositions. There were noticeable differences between the regions close to the flammability limits and for stoichiometric mixtures. The equilibrium model has been validated for varied temperatures and pressures representative of initial conditions that may be present in a reactor containment shell during meltdown accidents.

Explosion venting of air/hydrogen mixtures with equivalence ratios ranging from 0.4 to 6.0 was investigated in a small vented cylindrical vessel and the experimental results showed that the maximum internal overpressure initially increased with an increase in hydrogen equivalence ratio up to approximately 1.6 and subsequently decreased [1092]. The discrepancy between the maximum internal overpressure and the

vent burst pressure was high for equivalence ratios ranging from 1.0 to 2.0 but low for very lean or very rich mixtures. Buoyancy had a significant effect on the evolution of the internal flame bubble for very lean air/hydrogen mixtures only.

### 7.12.9 Liquid Oxygen/Liquid Hydrogen Mixture Detonability

In this encyclopedia, detonability of non-hypergolic mixtures of oxidizers with fuels can be discussed either under the heading of the oxidizer in *Encyclopedia of Oxidizers*, or the fuel in (this) *Encyclopedia of Liquid Fuels*, or in a future set along with non-hypergolic combinations of such oxidizers and fuels. There may be some overlap between these parts of the book. Many of the studies of the detonability of LOX/LH<sub>2</sub> also included experiments with LOX/RP-1 and comparisons of these two most widely used liquid propellant combinations.

The explosive hazard of mixtures of liquid hydrogen and solid air is less than what was initially feared. In small-scale experiments where liquid air was poured into liquid hydrogen and then ignited, in one case pouring 300 g of liquid air into 4.7 L liquid hydrogen, the mixture when ignited with a glowing wire would not detonate. It would detonate only if the liquid air had been standing in a Dewar flask for a while and had enriched itself with the lower boiling oxygen [500]. Air condensing into a reservoir of liquid hydrogen may be enriched in the lower boiling and more readily condensing oxygen.

Liquid hydrogen filled chambers are sometimes used adjacent to nuclear research reactors to moderate the flux of neutrons and create a collimated beam of low-energy neutrons. Negligent operation could allow air to leak into these chambers. Solid air/liquid hydrogen explosions have been carried out in a closed volume to assess the possible hazards of an explosion in such nuclear reactor experiment [1093]. Mixtures of solid air and liquid hydrogen are not shock sensitive, because they could not be made to detonate when hit by a falling hammer in a drop weight tester, not even at the highest drop height the apparatus was capable; however, mixtures of solid oxygen and liquid hydrogen are shock sensitive and detonated under the same conditions of mechanical impact [500, 1094, 1095]. Mixtures of solid air in liquid hydrogen were reported to be detonable for concentrations of less than 40% oxygen [1096].

The development of large launch vehicles has created safety concerns in the siting of test stands and launch pads. Thus, LOX/RP-1 launch vehicles are sited by using a TNT equivalent of 20% for quantities up to 226 000 kg (500 000 lb) and an equivalent of 10% for any excess over that amount; however, LOX/LH<sub>2</sub> launch vehicles were at one time sited using a TNT equivalent of 60% [1097]. Tests using 90.6 kg (200 lb) of LOX/RP-1 and LOX/LH<sub>2</sub> were made with spill test and simulated tankage configurations. The results indicated that the spill test method of investigation on which the TNT equivalent for LOX/LH<sub>2</sub> vehicles was based probably gave excessive yields and, therefore, may not be valid for this propellant combination. The tandem tank tests were made to provide information about the explosive yields occurring under condi-

tions more closely simulating various types of vehicle failures on the launch pad. The average yields for simulated destruct tests ranged from 0.6 to 1.6%, and those for the tests using a bulkhead failure mode ranged from 0.4 to 1.4%.

One series of tests with LOX and LH<sub>2</sub> was performed to simulate the conditions which might exist in the common bulkhead separating the two tanks in upper stages if the bulkhead would spring a leak [1098]. In a sealed bomb solid oxygen was pressurized with cold hydrogen at a little above 20 K and ignited with a glow plug. The cold mixture ignited only in 80% of the tests and required a substantial heat input of the order of 3–4 J. When the initial pressure was 12.16 kPa (0.12 atm), the pressure at the end of the reaction had risen 80-fold. Higher pressure rise was encountered if both reactants were gaseous at 83 K (–190 °C) to start with. The space between the two propellant tanks is not empty but filled with insulating material and the dimensions in the insulating layer are below the critical diameter for explosion propagation in O<sub>2</sub>/H<sub>2</sub>.

In the case of launch pad accidents, LOX and LH<sub>2</sub> or RP-1 may have an opportunity to pre-mix before they are ignited by an external source of ignition. The worst-case explosive yield of such explosions has been predicted by model experiments and by calculations [1095, 1097, 1099–1100]. The worst-case maximum explosive yield is predicted with delayed ignition about half-way through the propellant spill event, giving the propellants enough time to mix before they are ignited.

The explosive yield is proportional to the contact area between oxidizer and fuel as they begin to mix and before they are ignited. The primary purpose of the second phase of a test series was to compare the explosive yield of LOX/LH<sub>2</sub> explosions to those of LOX/RP-1 and N<sub>2</sub>O<sub>4</sub>/Ae-50 [1101]. The second series of 10 tests included two LOX/LH<sub>2</sub> tests at a contact area  $A_c = 2.33 \text{ m}^2$  (25.1 ft<sup>2</sup>), two tests were performed at  $A_c = 3.42 \text{ m}^2$  (36.8 ft<sup>2</sup>), and two tests were performed at  $A_c = 5.22 \text{ m}^2$  (56.2 ft<sup>2</sup>). Two LOX/RP-1 tests and two N<sub>2</sub>O<sub>4</sub>/Ae-50 tests were performed at the intermediate contact area  $A_c$  of 3.42 m<sup>2</sup> (36.8 ft<sup>2</sup>). As a reference for the tests and for calibration of the instruments, a series of unconfined 10, 25, 50, and 100 lb<sub>m</sub> trinitrotoluene (TNT) charges were detonated.

The yield produced by explosions of the LOX/LH<sub>2</sub> propellant system (after short ignition delay times) is similar to the yields produced by the N<sub>2</sub>O<sub>4</sub>/Ae-50 and the LOX/RP-1 propellant systems (all at the same contact area). The past practice of using much larger yield criteria for LOX/LH<sub>2</sub> than for LOX/RP-1 probably overrated the hazard of LOX/LH<sub>2</sub> relative to LOX/RP-1 for reasonable modes of launch-vehicle failure.

#### 7.12.10 Explosion Blast Overpressure from LOX/LH<sub>2</sub> Launch Mishaps

Spill and explosion tests using 200 lb of LOX/LH<sub>2</sub> were made with simulated tankage configurations. The results indicated that the spill test method of investigation on which the pre-1965 TNT equivalent for LOX/LH<sub>2</sub> vehicles was based probably gave excessive yields and, therefore, may not be valid for this propellant combination. It was

suggested that future investigations of liquid propellant blast hazards must simulate vehicle configurations and failure modes and that the pre-1965 LOX/LH<sub>2</sub> TNT equivalent used for siting should be re-examined [1097, 1102].

Project Pyro was an experimental program designed to obtain data useful for assessing the hazards from liquid propellant rocket explosions. The program was conducted at the Air Force Rocket Propulsion Laboratory, Edwards Air Force Base. The URS Corp., Burlingame, CA, established the overall design of the program, designed and constructed the test articles, and analyzed the data. The tests were conducted primarily with small propellant weights (200 and 1000 lb) under a variety of failure modes and geometry configurations. It was intended that this data, supplemented by a limited number of 25000 lb tests and two full-scale 94000 lb tests would then provide a basis from which explosive effects from operational vehicles might be predicted. The results from these tests were later analyzed statistically [1103]. See also [1095, 1104].

A generalized method was developed for predicting the blast and thermal environment resulting from explosions of the three most common liquid propellant combinations: LOX/RP-1, LOX/LH<sub>2</sub>, and NTO/Ae-50 [1105]. The blast prediction method took into account the fact that the explosive potential of a given liquid propellant combination in accidental failures is not a unique value but depends on the manner in which the propellants are brought together during the failure process and on the time of ignition after the start of mixing. The method provided a means for predicting the blast environment as a function of the following system characteristics: tank configuration, propellant type, propellant weight, nature of failure mode and ignition time.

Three independent methods which have been worked out theoretically and verified through experimental procedures were used to predict explosive yield values for liquid rocket propellants. All three gave the same end result even though they utilized different parameters and procedures. The three methods were: **(1)** mathematical model, **(2)** seven chart approach and **(3)** critical mass method [1099, 1106, 1107]. The methods were used and their value demonstrated in analyzing real problems, among them the destruct system of SATURN 5, and early configurations of the Space Shuttle.

The TNT equivalency criterion for LOX/LH<sub>2</sub> explosions in effect prior to 1971 was re-evaluated [1108]. The study addressed the static, on-pad phase of the space shuttle launch operations and was performed to determine whether the use of a TNT equivalency criterion lower than that used as of 1971 (60%) could be substantiated. The large quantity of propellant on-board the space shuttle,  $4 \times 10^6$  lb, was considered of prime importance to the study. A qualitative failure analysis of the space shuttle on the launch pad was made because it was concluded that available test data on the explosive yield of LOX/LH<sub>2</sub> propellant was insufficient to support a reduction in the present TNT equivalency value, considering the large quantity of propellant used in the Space Shuttle. The failure analysis had two objectives: The first was to determine whether a failure resulting in the total release of propellant could occur. The second was to determine whether, if such a failure did occur, ignition could be delayed long enough to allow the degree of propellant mixing required to produce an explosion of

60% TNT equivalency since the explosive yield of this propellant is directly related to the quantities of LOX and LH2 mixed at the time of the explosion. The analysis indicated that the occurrence of such a failure is unlikely and that a TNT equivalency of 20% would be a more realistic value for the static, on-pad phase of the Space Shuttle launch operations [1102].

Explosions were examined which may result from the mixing of liquid oxygen and liquid hydrogen (LOX/LH2) such that the reactants are confined by a rocket body shell such as the CENTAUR upper stage [1109]. Explosions which were confined by the ground surface were also studied, with results reported elsewhere. Initial attempts to predict the reported Pyro experimental results were unsuccessful. A new reaction energy addition hypothesis was then developed and tested. The results provided reasonable agreement with the experiments both in the near and far field.

An engineering risk assessment of the conditions for massive explosions of cryogenic LOX/LH2 rockets during launch accidents was based on the analysis of experimental data from purposeful rupture experiments with liquid oxygen and hydrogen tanks and on an interpretation of these data via analytical semi-quantitative estimates and numerical simulations of simplified models for the whole range of the physical phenomena governing the outcome of a propellant-tank breach [1110]. The following sequence of events was reconstructed in a computer model: rupture of fuel tanks, escape of the fluids from the ruptured tanks, liquid film boiling, fragmentation of liquid flow, formation of aerosol oxygen and hydrogen clouds, mixing of the clouds, droplet evaporation, self-ignition of the aerosol clouds and aerosol combustion. The power of the explosion was determined by a small fraction of the escaped cryogenes that became well mixed within the aerosol cloud during the delay time between rupture and ignition. Several scenarios of cavitation-induced self-ignition of the cryogenic hydrogen/oxygen mixture were discussed. The explosion parameters in a particular accident are expected to be highly varied and unpredictable due to randomness of the processes of formation, mixing, and ignition of oxygen and hydrogen clouds. Under certain conditions rocket accidents may result in very strong explosions with blast pressures from a few atm up to 100 atm.

A Liquid Propellant Fragment Overpressure Acceleration Model that produced a representative debris cloud from an exploding liquid-propellant launch vehicle was applied to the Core Stage of the NASA Space Launch System (SLS) launch vehicle [1111]. A combination of probability density functions based on empirical data from rocket accidents and applicable tests, as well as SLS specific geometry were combined in a MATLAB script to create unique fragment catalogues. By accelerating the debris catalogue with the blast model for LOX/LH2 explosions, the result was a fully integrated code that modeled the destruction of the core stage at a given point in its trajectory and generated hundreds of individual fragments with initial imparted velocities. The blast model provided the blast size (radius) and strength (blast wave overpressure) as probabilities based on empirical data and anchored with analytical work. The objective was to quantify the risk for a multitude of potential core stage destruct scenarios.

Examples included the effect of warning time on the survivability of an escaping crew capsule or the maximum fragment velocities generated by the ignition of leaking propellants in internal cavities.

#### 7.12.11 Pre-Mixed Solid Oxygen/Liquid Hydrogen Detonations

Most of the published information on explosive yield estimation was dealing with either LOX/RP-1 or LOX/LH<sub>2</sub>. The main concern is about the failure of the dome separating the LOX and LH<sub>2</sub> tanks in launch vehicles. Initially the concern was limited to simulating failures in the CENTAUR upper stage, but then the concern expanded to include the Space Shuttle STS external tank and more recently, the DELTA, H-II, ARIANE-5, and SLS launch vehicles [943].

The concern about the handling hazard associated with the potential explosibility of mixtures of solid oxygen with high-pressure gaseous hydrogen provided the incentive for a phase equilibria and thermodynamic study [57]. The specific concern was (is) with the behavior of oxygen which is present as a trace impurity (concentration of a few parts per million) in a high-pressure hydrogen stream which is being cooled. Oxygen crystallizes during the cooling process when the saturation concentration of oxygen is reached. The exact temperature depends upon the total pressure and the oxygen concentration. For low concentrations, the temperature is below the triple-point temperature of 54.37 K (−361.8°F). The possibility always exists that solid oxygen may concentrate in heat exchangers and other process components which are at temperatures lower than the triple point. Even at very low concentrations, the oxygen may accumulate and cause hazardous conditions. The data on the solid-vapor equilibria of the oxygen/hydrogen system are, therefore, of considerable interest for the safe design and operation of hydrogen liquefaction equipment. While accidental detonations of LOX/LH<sub>2</sub> can have disastrous consequences, controlled detonation of O<sub>2</sub>/H<sub>2</sub> in pulsed or spinning detonation engines is actively investigated in an effort to achieve higher specific impulse.

Direct initiation and propagation of detonation through a cryogenic two-phase flow of liquid oxygen droplets in cold gaseous hydrogen at 100 K were experimentally investigated [1112]. The influence of droplet size distribution was characterized in a cryogenic gaseous hydrogen and liquid oxygen two-phase flow. Droplet sizing and detonation experiments were conducted by varying different parameters: distance from the injector, helium and hydrogen mass flow rates, global equivalence ratio, and addition of gaseous nitrogen. Droplet size distributions revealed quick vaporization of the smallest droplets of the cryogenic jet. Results in terms of wave velocity, pressure, and detonation cells showed that a detonation wave can be directly initiated, with a propagation wave velocity of 20% higher than the predicted C-J value. Cell size measurements showed that the mixture sensitivity was not affected by the presence of droplets. Addition of gaseous nitrogen reduced the peak pressure only slightly but the detonation velocity was reduced by about 30%.

## 8 Toxic Properties of Hydrogen

Hydrogen is not toxic; however, because it does not sustain breathing, inhalation of hydrogen will lead to a lack of oxygen and suffocation. Because warm hydrogen is much lighter than air it is unlikely that oxygen-depleted spaces at ground level are formed as the result of venting hydrogen. This is unlike the asphyxiation hazard from venting of nitrogen in enclosed spaces.

The main hazard to the operators during handling of liquid hydrogen is frostbite due to freezing of tissue if liquid hydrogen is accidentally spilled on the skin or if an operator accidentally comes into contact with a cold line with bare skin. Moist skin, like fingers on a bare hand touching a cold surface will instantly freeze onto the surface and is only difficult to remove by pouring on copious amounts of lukewarm water. Frostbite caused by liquid hydrogen is similar to frostbite caused by liquid oxygen or liquid nitrogen.

## 9 Accident History of Hydrogen

Section “Liquid Hydrogen Transportation Accident History” dealt with transportation accidents during the transportation of liquid hydrogen in tank cars, rail cars, and barges. These accidents may or may not have resulted in ignition of the spilled liquid or released gas. Accidents with LOX and liquid hydrogen were included in a summary of launch vehicle accidents, including launch failures and launch aborts [1113].

In the accident history with LOX and LH2 there are at least three incidents with liquid propulsion systems containing a combination of LOX and LH2. Two propellant tank confinement by outer shell (interior tank bulkhead rupture) failure accidents occurred during preparations for static tests of SATURN-V vehicle propulsion stages in 1964 and 1967. In addition, a full-scale SATURN stage was also tested to similar confinement-by-missile failure during Project Pyro. The first LOX/LH2 static test accident involved a fully loaded S-IV third stage of a SATURN V launch vehicle [1114]. The stage contained approximately 84000 lb of LOX and 17000 lb of LH2. An explosion occurred 5 s before ignition of the engine. The immediate cause of the failure was determined to be overpressurization of the liquid oxygen tank, which resulted in either rupture of the common bulkhead between the LOX and LH2 or nearly simultaneous external rupture of both propellant tanks with subsequent mixing. In either case, the failure simulated a confinement-by-missile failure mode as defined in Project Pyro. All available evidence indicated that ignition occurred almost immediately upon contact of the two propellants, with very limited mixing of the hydrogen and oxygen. Spontaneous ignition has also been observed in many large-scale controlled LOX-LH2 tests during Project Pyro and other test programs. TNT equivalence of the LOX-LH2 explosion was estimated during the post-accident investigation by considering damage to specific structures [1102]. One estimate was obtained based on damage to a lightweight

sheet metal building located 63.8 m (210 ft) from the test stand. Damage consisted of wrinkling/slight crushing of the metal wall and roof panels, buckling/deflecting of structural members in the roof to about 5 cm (2 in.), and breaking of several windows on the wall facing the explosion and one window on the opposite wall. Overpressure required to produce this magnitude of damage was estimated to be about 34 kPa (5 psi) (reflected) and 17 kPa (2.5 psi) (side-on) yielding a TNT equivalent weight for the explosion of approximately 344 kg (760 lb<sub>m</sub>). Another estimate was based on the 30-cm (12 in.) permanent deflection observed in a structural steel I-beam of the test stand located approximately 3.9 m (13 ft) from the center of explosion. The estimated TNT equivalent weight based on overpressure impulse for this type of damage was about 453 kg (1000 lb<sub>m</sub>). TNT equivalence was also estimated from glass breakage which occurred at distances up to approximately 334 m (1100 ft). The agreement between estimates derived independently from different effects was very good and all of the analyses converged to an average equivalent weight value of 494 kg (1090 lb<sub>m</sub>) TNT. Based on the total LOX-LH2 propellant load, the average TNT equivalence for the event was estimated to be about 1.1%, with a maximum of about 1.4%. Fragments from the event were thrown to a maximum distance of 334 m (1100 ft).

The other LH2-LOX static test explosion occurred with a SATURN-V S-IVB third stage. The total propellant load involved in this incident was about 104643 kg (231000 lb<sub>m</sub>) (5:1 mass ratio of oxidizer to fuel). The failure also simulated a confinement-by-missile mixing mode. Again, TNT equivalence was estimated based on damage observed from the explosion. The estimated equivalent weight was between 906 and 1132 kg (2000 and 2500 lb<sub>m</sub>) yielding a calculated TNT equivalence again of approximately 1%. Fragments from this event were thrown to a maximum distance of 300 m (984 ft). These data are also consistent with estimates of TNT equivalence for LH2-LOX explosions observed in other large scale test programs.

A full-scale SATURN upper stage containing 34428 kg LOX and 6886 kg LH2 (76000 lb<sub>m</sub> LOX and 15200 lb<sub>m</sub> LH2) was tested to common bulkhead rupture in Project Pyro. Bulkhead rupture was accomplished using a 46 cm (18 in.) diameter explosively driven ram cutter assembly. Ignition of the propellants occurred spontaneously at about 183 ms after rupture of the bulkhead. Air blast data recorded in the test indicated a maximum TNT equivalence of 3.5% based on overpressure and 6.8% based on overpressure impulse. Fragment dispersion ranged to a maximum of 300 m (984 ft).

This section deals with all other types of accidental releases of liquid or gaseous hydrogen, some of which lead to autoignition by buildup of electrostatic charge in the flowing gas [1115].

### 9.1 Liquid Hydrogen Leaks without Ignition

A US Department of Energy-sponsored web site maintains a list of hydrogen incidents and as an educational tool, informs about lessons learned in trying to prevent recurrence of such disasters [1116]. Several incident examples from the web site are quoted here

While disconnecting a liquid  $H_2$  fill line from a liquid  $H_2$  trailer, liquid  $H_2$  escaped, frost-burning a second man who was holding the hose. The man was burned on his hands and on his stomach. The cause of the accident was that the liquid  $H_2$  shut off valve was partially open, but both men assumed it was closed. Prescribed clothing was being worn.

### 9.2 Liquid Hydrogen Tank Accidental Venting without Ignition

A ruptured disk on a liquid hydrogen tank failed prematurely, which caused the tank to vent its entire gas contents through the tank's vent stack while the pilot flame was not lit [1117]. Venting was very loud and formed a condensed moisture cloud visible from the top of the stack. Liquid air was also visible coming off the stack. Venting ceased after approximately 5 minutes. Important to note that the safety system functioned as intended. Most prevalent learning is that liquid air will form and fall off the vent stack due to very high flow of very cold gas when the relief systems are flowing at capacity. Liquid air may also splash off flanges or other pieces and will cause a small vapor cloud as it falls from the stack. Falling raining liquid air was mistaken for liquid hydrogen during the event.

### 9.3 Liquid Hydrogen Fires

In this case, a liquid hydrogen tank incident caused a second incident. While attempting to replace a rupture disk in an  $LH_2$  vessel,  $GH_2$  gas was released and ignited. In fighting the fire, liquid  $N_2$  was sprayed by the incident response team onto a second  $LH_2$  vessel located nearby. This resulted in cracking of the outer mild steel vacuum jacket. The loss of the vacuum caused a rapid increase in pressure and rupture of the burst disk of the second vessel.  $H_2$  boiled off and was burned in the fire. The cause of the problem was that the rupture disk was being replaced with a load of liquid  $LH_2$  in the vessel and no separating inerting gas. The  $H_2$ -air mixture was probably ignited by static discharges. Rupture of the second vessel burst disk was caused by the low-temperature exposure embrittlement of the mild steel vacuum jacket.

In another incident, a rupture disc blew on a  $75\text{-m}^3$  (20000 gallon) liquid hydrogen tank, causing the vent stack to exhaust cold gaseous hydrogen [1118]. Emergency responders were called to the scene. To stabilize the tank, the remaining hydrogen was

removed from the tank except for a small volume in the heel of the tank that could not be removed manually. The tank vacuum was lost. Firemen sprayed the tank with water and directed a stream onto the fire exiting the vent stack. The water was channeled directly into the open vent stack, and the exiting residual hydrogen gas (between 20 and 32 K = −423 and −402 °F) caused the water in the vent stack to freeze. The water freezing caused the vent stack to be clogged, disabling the only exit for the cold hydrogen gas. After a time, the residual hydrogen gas in the tank warmed up, causing the tank to overpressurize and rupture with an explosion known as a BLEVE (boiling liquid expanding vapor explosion) and ignite.

# Hydronitrogen Compounds

## Hydronitrogen Compounds

*Encyclopedia of Liquid Fuels* contains six chapters dealing with hydronitrogen compounds and four chapters dealing with hydrazines: “Ammonia” is the simplest hydronitrogen, the chapter “Hydrazine” deals with the parent inorganic compound hydrazine, while “Alkylhydrazines” deals with alkylhydrazines other than methylhydrazine and dimethylhydrazines, which are covered in the chapters “Methylhydrazine” and “Dimethylhydrazines,” respectively. The latter two chapters are about alkyl-substituted hydronitrogen compounds. Amines, amides, and imides are not counted as hydronitrogen compounds, although many of them contain N–H bonds.

Besides ammonia  $\text{NH}_3$ , hydrazine  $\text{H}_2\text{NNH}_2$ , hydrazoic acid  $\text{HN}_3$ , and their salts, there are several other hydronitrogen compounds under consideration as rocket propellants, but they are all very unstable and occur only very briefly as transients and intermediates in the decomposition of any of the aforementioned more stable hydronitrogens. It is unlikely that any of the other hydronitrogen compounds could ever be used as rocket propellants, but we include them in our discussion of rocket propellants because of their close relationship to ammonia and hydrazine. Some of these unusual hydronitrogen compounds may form in the interiors of gaseous planets at very high pressures and eventually diffuse to the surface, contributing to the hydronitrogens we can observe in the outer atmospheres of some of the giant gaseous planets. Much of the research into higher ( $\text{N} > 2$ ) polynitrogen and hydronitrogen compounds was motivated by the search for more energetic rocket propellants. If higher hydronitrogen compounds could be synthesized, they could be stored and stabilized in ammonia solution or hydrazine solution.

The introduction to the second edition (published in 2001) of Schmidt’s hydrazine book [1] contains a section on other hydronitrogen compounds, also called nitrohydrogen compounds. That section can suffice as a starting point for information on this subject; we try to expand upon it and update it here.

In this *Encyclopedia of Rocket Propellants*, a future set on solid propellants will contain a chapter on high-nitrogen compounds, most of which are organic compounds that contain at least one carbon in addition to nitrogen, and most of those are solids. The search is on for all-nitrogen compounds other than dinitrogen, but so far, all synthesis efforts have resulted in premature decomposition of the desired compounds. Theoretical computations to predict the existence and stability of all-nitrogen compounds will be described in the chapter on high-nitrogen compounds. Similar computations have been done for higher hydronitrogen compounds. The search for new all-nitrogen compounds and the search for new hydronitrogen compounds are related and go on in parallel.

The current chapter on hydronitrogen compounds was at one time part of the hydrazine chapter, but it had to be split off because the hydrazine chapter needed to be shortened. The chemistry of hydrazine is closely related to the search for other hydronitrogens with more than two nitrogens linked together. The analogy of hydronitrogens with hydrocarbons, which can form long C—C chains, is deceiving. When comparing ammonia with methane and then comparing hydrazine with ethane, the analogy ends just about right there at hydrazine, with two atoms in the N—N chain. In contrast to carbon, nitrogen does not have the capability to form stable long-chained (*catenated*) and branched or closed-ring compounds without the participation of carbon or other heteroelements. The only known stable hydronitrogens are ammonia, hydrazine, hydrogen azide (hydrazoic acid), and their salts. One would hesitate to refer to hydrogen azide as a “stable” compound because it is metastable in its pure form and is known to explode most violently. However, it is at least stable enough to be characterized as a compound by itself. Another hydronitrogen compound of interest is hydroxylamine  $\text{NH}_2\text{OH}$ , but this contains one other hetero element, oxygen. Hydroxylamine, the free base, deserves another monograph on its own, and is included in the chapter “Hydroxylammonium Salts” in of the *Encyclopedia of Oxidizers* as the parent of a series of energetic salts that are of interest as rocket propellants.

Inorganic hydronitrogen compounds that are anticipated to exist include triazane  $\text{H}_2\text{N—NH—NH}_2$ , CAS RN [14451-01-5], and tetrazane  $\text{H}_2\text{N—NH—NH—NH}_2$ , CAS RN [6054-69-9]. Many organic triazenes, tetrazanes, and tetrazenes where the hydrogen is replaced by alkyl or aryl groups are known. These are polynitrogen open-chain molecules where one or more of the hydrogens have been replaced by organic groups. Aromatic triazenes and tetrazenes are stabilized by the resonance of the azo groups with the electron system of the benzene ring. However, the inorganic unsubstituted or unprotonated parent compounds are unstable, and all attempts at their preparation have failed so far. In analogy to the hydrocarbon series of alkanes and alkenes, a saturated and an unsaturated series of compounds can be defined, the azanes and azenes. The latter group has one or more  $\text{—N=N—}$  nitrogen–nitrogen double bonds in the molecule.

## 1 High-Pressure Behavior of Hydronitrogen Compounds

Starting with gaseous elemental dinitrogen and dihydrogen, if these two gases are subjected to higher and higher pressures, which hydronitrogens will form, and which will persist even after the pressure is relieved? The Haber–Bosch synthesis of ammonia from its elements is a chemical process of vital importance for agriculture and the chemical industry. Twenty percent of the world’s population could not survive without fertilizer-supported agriculture, a process that starts with nitrogen and hydrogen under pressure. The formation of ammonia depends on the presence of catalysts and

has been thoroughly investigated. What if the two gases are compressed in the absence of catalysts to beyond their points of liquefaction and solidification? Ammonia and/or hydrazine and/or yet unknown hydronitrogens are likely to form under these extreme conditions. These questions are of interest in the study of planetary cores and atmospheres, especially those of Jupiter, and have been studied both experimentally and theoretically [2, 3]. Even if such previously unknown hydronitrogen compounds do form at very high pressure, the question of whether they survive after the pressure is relieved remains. If they can be stabilized, such as in a matrix of frozen nitrogen, they would be even more energetic than hydrazine.

Binary nitrogen/hydrogen mixtures subjected to very high pressures were analyzed using Raman spectroscopy, synchrotron XRD, synchrotron IR microspectroscopy, and visual observation [4]. A eutectic-type binary phase diagram with two stable high-pressure van der Waals compounds, identified as  $(\text{N}_2)_6(\text{H}_2)_7$  and  $\text{N}_2(\text{H}_2)_2$ , was found. The former represents a new type of van der Waals host–guest compound in which hydrogen molecules are contained within channels in a nitrogen lattice. This compound showed evidence of a gradual pressure-induced change in bonding from van der Waals to ionic interactions near 50 GPa, forming an amorphous dinitrogen network containing ionized ammonia in a room-temperature analogue of the Haber–Bosch process. Hydrazine was recovered on decompression.

Phase changes that occur in hydrazine under very high pressures are discussed in the chapter “Hydrazine” in the present *Encyclopedia of Liquid Fuels*.

The formation of nitrohydrogen compounds at pressures up to 50 GPa and their structural transformations upon applying and releasing pressure were predicted using density functional theory and evolutionary algorithms [5]. Nitrogen–hydrogen structures with N:H ratios of 3:1, 4:1, and 9:1 were simulated at high pressures (10–50 GPa). Stable crystalline structures with high symmetry and covalent bonds were predicted that had infinitely long chains or two-dimensional nitrogen–hydrogen sheets. The structure with an N:H ratio of 4:1 was found to be metallic at 50 GPa. Some crystalline phases stabilized by high pressure may exist as metastable structures of high symmetry and high mass density after lowering the pressure from 50 GPa down to 10 GPa.

Theory predicts a very diverse high-pressure chemistry of hydronitrogens, with the existence of many  $\text{N}_x\text{H}_y$  compounds [6]. The stability of these phases under pressure was investigated by the compression of  $\text{N}_2/\text{H}_2$  mixtures of various compositions. A eutectic-type  $\text{N}_2/\text{H}_2$  phase diagram with two stoichiometric van der Waals compounds,  $(\text{N}_2)_6(\text{H}_2)_7$  and  $\text{N}_2(\text{H}_2)_2$ , was discovered. The structure of the  $\text{N}_2(\text{H}_2)_2$  compound and chemical changes under a pressure cycle up to 60 GPa and back to ambient conditions were characterized using Raman spectroscopy. An  $\text{N}_2(\text{H}_2)_2$  single crystal was grown from a 1:2  $\text{N}_2/\text{H}_2$  mixture and its crystalline structure was determined using synchrotron X-ray diffraction. Like the solid  $(\text{N}_2)_6(\text{H}_2)_7$ ,  $\text{N}_2(\text{H}_2)_2$  has a remarkable host/guest structure containing orientationally disordered  $\text{N}_2$  molecules with spherical, ellipsoidal, and planar shapes. Above 50 GPa,  $\text{N}_2(\text{H}_2)_2$  was

found to undergo a chemical reaction. The reaction products were determined to be from the azane family, with  $\text{NH}_3$  as the main constituent, along with molecular nitrogen. Upon decreasing the pressure, the reaction products were found to react in such a way that below 10 GPa, hydrazine was the sole azane detected. Observed down to the opening of the diamond anvil cell, the formation of metastable hydrazine instead of the more energetically favorable ammonia was surprising and could change the current view of Jovian planetary atmospheres, in which ammonia was previously assumed to be the only stable hydronitrogen molecule.

Compressing lithium metal embedded in a matrix of solid  $\text{N}_2$  to very high pressures (45 GPa) resulted in lithium pentazolate  $\text{LiN}_5$  formation [7]. The observation by Raman spectroscopy of vibrational modes unique to the cyclo- $\text{N}_5^-$  anion was the signature of the formation of  $\text{LiN}_5$ . Mass spectroscopy experiments confirmed the presence of the pentazolate anion in the recovered compound. A monoclinic lattice was obtained from XRD measurements, and the unit cell volume of the  $\text{LiN}_5$  compound under pressure was in good agreement with theoretical calculations.

## 2 Homocyclic Hydronitrogen Compounds

Homocyclical-nitrogen ring compounds (as opposed to the heterocyclic compounds discussed in the chapter “Heterocyclic and Heterocycloaliphatic Amines” in this volume) are unstable and difficult to obtain. They can be stabilized by adjacent fused aromatic rings.

### 2.1 Three-Membered Ring Homocyclic Hydronitrogen Compounds

It is difficult enough to obtain carbon-based three-membered ring compounds, and some of those, e.g., ethylene oxide, have been tested as monopropellants. Ethyleneimine ( $\text{C}_2\text{H}_5\text{N}$ , aziridine) would be a good fuel. Diazomethane ( $\text{CH}_2\text{N}_2$ , diazirine) is unstable and handled only in solution. Triaziridine ( $\text{N}_3\text{H}_3$ ) can be stabilized by adsorption on silver zeolites, and organic triaziridines with various substituents have been made. It is unclear if stable isomers of triaziridine exist [8].

Portions of the  $\text{N}_3\text{H}_3$  singlet potential energy surfaces corresponding to triaziridines, azimines, and triazenes have been calculated by *ab initio* methods [9]. Minima and transition states were located by force gradient geometry optimization. The configuration at the three N atoms in triaziridines is pyramidal. The N–N bonds in triaziridine are longer and weaker than those in hydrazine. *trans*-Triaziridine has better stability than *cis*-triaziridine. In azimine, all six atoms are in the same plane. There are three stereoisomers. In triazene, all six atoms are in the same plane. There are two stereoisomers.

Of all the  $(\text{NH})_n$  ring-shaped hydronitrogens, triaziridine, with  $n = 3$ , if it existed, would have the highest strained ring energy [10]. Thermochemical properties of two molecules containing three nitrogen atoms in a ring, triaziridine and triazirine, were calculated [11]. Predicted enthalpies of formation of *trans*-triaziridine ranged from +405.0 to +418 kJ/mol.

Nitrotriaziridines would be nitramines without a carbon skeleton, like RDX with the  $-\text{CH}_2-$  linkages removed. It was hoped that the electron-drawing ability of the  $-\text{NO}_2$  groups would stabilize the three-membered ring, but, at the same time, steric hindrance from the presence of more than one bulky  $-\text{NO}_2$  group in a crowded space near the small ring makes these compounds less stable. Predicted enthalpies of formation of nitrotriaziridine, dinitrotriaziridine, and trinitrotriaziridine are +486.79, +606.64, and +706.38 kJ/mol, so they truly are highly energetic compounds, but these high numbers also indicate that these compounds would be unstable [12]. These compounds were not included in the chapter on nitramines because they do not exist.

## 2.2 Four-Membered Ring Homocyclic Hydronitrogen Compounds

Tetrazetidine,  $\text{N}_4\text{H}_4$ , CAS RN [58674-00-3], which consists of four NH groups linked in a square four-membered ring, is an isomer of ammonium azide  $\text{NH}_4\text{N}_3$ , an isomer of aminoaziridine, CAS RN [176109-57-2], a three-membered ring with an amino group attached, and an isomer of tetrazene-2,3, CAS [RN 54410-57-0], which has an azo group with two amino groups  $\text{H}_2\text{N}-\text{N}=\text{N}-\text{NH}_2$ .

Tetrazetidine    Aminoaziridine    Tetrazene-2,3

There have been many attempts to convert ammonium azide to some of its isomers by subjecting it to very high pressures. Ammonium azide was the preferred starting reactant for such investigations. It does not appear that any of these isomers are more stable or more suitable as rocket propellants than ammonium azide itself. Similarly, hydrazinium azide has been subjected to very high pressures in the search for other hydronitrogens.

First-principles and *ab initio* calculations were made to investigate the structural, elastic, and electronic properties of  $\text{N}_4\text{H}_4$  compounds, with the ring compound compared to its straight-chain analogs [13–16]. The calculated structural parameters of three structures were in agreement with the available theoretical and experimental data. The most stable  $\text{N}_4\text{H}_4$  isomer is the straight-chain tetrazene-2,3,  $\text{H}_2\text{N}-\text{N}=\text{N}-$

NH<sub>2</sub>. The independent elastic constants, bulk moduli, shear moduli, Young's moduli, and Poisson ratios of the three structures were calculated and agreed with predicted elastic and mechanical properties. The electronic band structures, densities of states, and charge density distributions of the three structures indicated that there are covalent N—N and N—H bonds. In a computational study of the pressure-induced phase transition in the hydronitrogen compound N<sub>4</sub>H<sub>4</sub>, a tetragonal structure with a space group of *P4<sub>2</sub>/n* was mechanically stable and ductile [17]. With increasing pressure, the phase transition pressures were 5.6, 15.0, 30.0, and 69.2 GPa.

### 3 Hydronitrogens Derived from Compressed Ammonium Azide

Ammonium azide, NH<sub>4</sub>N<sub>3</sub>, is a hydronitrogen that is relatively stable at room temperature and makes a good starting point in the attempted synthesis of higher hydronitrogens. The preparation and properties of ammonium azide are summarized in the chapter "Azides and Azido Compounds" in this publication, the *Encyclopedia of Liquid Fuels*.

A combined theoretical and experimental study of the high-pressure behavior of ammonium azide using density functional theory considered the relative thermodynamic stability of the material with respect to two other crystal phases, (NH)<sub>4</sub> and *trans*-tetrazene [18, 19]. Raman spectra of NH<sub>4</sub>N<sub>3</sub> were measured at pressures up to 71 GPa at room temperature. There was no evidence of a phase transition to either tetrazene or tetrazetidine (NH)<sub>4</sub>.

The transformation of hydrazinium azide into molecular N<sub>8</sub> has been investigated at high pressures (up to 68 GPa) using confocal micro-Raman spectroscopy and synchrotron powder XRD [20]. The results showed that HA undergoes a structural phase transition from solid HA-I to HA-II at 13 GPa that is associated with the strengthening of hydrogen bonding, and then to N<sub>8</sub> at 40 GPa. When working with ammonium azide, one must remember that it is detonable and toxic [21].

#### 3.1 Five-Membered Ring Homocyclic Hydronitrogen Compounds

It appears that the electronic structures of certain five-membered nitrogen rings could be isoelectronic with that of benzene and thus possess aromaticity-supported stability. The stability of pentazole rings would be improved by the presence of adjacent aromatic rings to share the electron cloud with.

The short-lived existence of tetrazolylpentazole has been shown using low-temperature <sup>15</sup>N/<sup>1</sup>H NMR spectroscopy [22]. Tetrazolylpentazole was identified as an intermediate in the reaction of tetrazolediazonium chloride with lithium azide by low-temperature <sup>15</sup>N NMR spectroscopy. The decomposition of <sup>15</sup>N-labeled

tetrazolylpentazole to form  $^{15}\text{N}$ -labeled tetrazole azides and dinitrogen was followed by low-temperature  $^{15}\text{N}$  NMR spectroscopy.

The possibility of the existence of cyclopentazane, which is a polynitrogen compound with a formula of  $\text{N}_5\text{H}_5$ , has been examined, and it has been compared to the pentazolate anion, which is an all-nitrogen aromatic compound with a formula of  $\text{N}_5^-$  [23]. The syntheses of various arylpentazoles were followed by oxidative or reductive paths to the pentazolate anion. Polynitrogen-based compounds – triazanes and azimines – were then used in attempts at cycloaddition, which were hoped would lead to the cyclopentazane. Complexing polynitrogen compounds with various metal cations may result in more stable compounds.

### 3.2 Pentazolate Salts

The cyclo- $\text{N}_5$  molecule was synthesized for the first time by the reaction of benzenediazonium chloride with lithium azide in methanol at 233 K ( $-40^\circ\text{C}$ ), giving a phenylpentazole. In this compound, the  $\text{N}_5$  ring was covalently bonded to a larger aromatic ring molecule. XRD measurements showed that cyclo- $\text{N}_5^-$ , an analog of the cyclopentadienyl anion  $\text{C}_5\text{H}_5^-$ , is aromatic, with N–N bond lengths of 1.3–1.35 Å, intermediate between those of single (hydrazine, 1.45 Å) and double (*trans*-diazene, 1.25 Å) nitrogen bonds [24].

The existence of the cyclo- $\text{N}_5^-$  anion was proven in 2002 by electrospray ionization mass spectroscopy [25]. This anion is isoelectronic with the cyclopentadienide anion, and one could envision a wide array of inorganic ferrocene-type chemistry using cyclo- $\text{N}_5^-$ . The pentazolate anion has been generated from *p*-hydroxyphenylpentazole and identified by electrospray ionization mass spectrometry [26]. Whereas at low collision voltages the *para*-phenoxyphenylpentazole anion undergoes stepwise  $\text{N}_2$  elimination, generating the corresponding azide and nitrene, at high collision voltages the  $\text{N}_5^-$  anion is formed. Fragmentation of the pentazolate anion produces the  $\text{N}_3^-$  anion as the principal negative ion. It was demonstrated that under suitable reaction conditions, the C–N bond in a phenylpentazole can be selectively broken while conserving the pentazole ring, thus providing a potential synthetic route to the pentazole anion. Once the existence of the pentazolate anion in the gas phase was proven, the next target was to obtain and stabilize it in bulk in solution. Reports [27] of a bulk synthesis of  $\text{N}_5^-$  were later shown to be in error [28, 29].

Theoretical calculations showed that  $\text{N}_5^-$  favors the formation of  $\sigma$ -complexes over  $\pi$ -complexes, resulting in a loss of aromaticity for  $\text{N}_5^-$  and facilitating  $\text{N}_2$  elimination. To circumvent this problem, the plan was to complex the cations with crown ethers. The resulting flat, bulky cations were expected to favor sandwich structures and  $\pi$ -bonding.

Isolating the  $N_5^-$  anion proved to be difficult, and it was not until 2002 that  $N_5^-$  was obtained in the gas phase for the first time by cleaving the C–N bonds in substituted phenylpentazoles [25, 26]. However, the free acid pentazole  $HN_5$  has not yet been successfully isolated. In 2017, a breakthrough was made in polynitrogen chemistry with the synthesis of  $N_5^-$  in the condensed phase at ambient pressure as part of a metal–organic framework. The pentazole was prepared in a THF solution with sodium and was reported to be stable below 233 K ( $-40^\circ\text{C}$ ) [30, 31]. The main method for producing standalone  $N_5^-$  was through the cleavage of the C–N bond in arylpentazoles [32] and then by stabilizing the anion with various other cations such as hydronium, ammonium, or water as well as metal cations such as sodium, cobalt, iron, or manganese. Several solid saline compounds such as  $(N_5)_6(H_3O)_3(NH_4)_4Cl$  (stable below 390 K =  $117^\circ\text{C}$ ),  $Co(N_5)_2(H_2O)_4 \cdot 4H_2O$  [31, 32] (stable at room temperature), and the hydrate  $[Na(H_2O)(N_5)]_2H_2O$ ,  $[M(H_2O)_4(N_5)_2]_4H_2O$  ( $M = Mn, Fe, \text{ and } Co$ ) (stable near to 373 K =  $100^\circ\text{C}$ ) were also synthesized [33]. Although it is not clear what the energy densities of these materials are, the results demonstrated that the  $N_5^-$  anion is stable enough to exist near ambient conditions in the solid state.

Planar  $N_x$  systems such as cyclo- $N_5^-$  and  $N_5^+$  tend to be more stable than nonplanar systems such as the neutral cyclo- $N_6$ . It was proposed that the key to stabilization is the separation of the  $\sigma$ - and  $\pi$ -electron systems [34]. In both cyclo- $N_5^-$  and  $N_5^+$ , a six- $\pi$ -electron system is created upon either adding an electron to or removing an electron from the cyclo- $N_5$  radical. Judicious addition of oxygen atoms to polynitrogen ring compounds such as cyclo- $N_4$  and cyclo- $N_6$  can increase their thermodynamic and kinetic stabilities, which is accompanied by only a small reduction in their efficiency as high-energy-density materials.

It was hoped that derivatives of pentazole could lead to new high-energy-density materials to be used as rocket propellants or explosives. However, these molecules are potentially hazardous because of their high formation enthalpies and weak N–N bonds. Possible routes for the synthesis of nitro and azido derivatives of pentazole and their mono- and dioxides have been explored using quantum chemical methods [35]. Reaction pathways have been investigated in detail, with emphasis on locating transition states and obtaining a reliable treatment of solvent effects.

A thorough survey of energetic polynitrogen compounds at high pressure was provided in [36, 37]. XRD patterns and corresponding Raman spectra were calculated for several candidate structures. Cesium pentazolate was synthesized by compressing and heating cesium azide  $CsN_3$  and  $N_2$  precursors in a diamond anvil cell.

### 3.2.1 Ammonium Pentazolate

After the discovery of lithium pentazolate  $LiN_5$ , the search started for other pentazolate salts. The formation of ammonium pentazolate  $NH_4N_5$  is predicted by computational methods, but the compound has not yet been isolated.

The existence of pentazole ( $\text{N}_5\text{H}$ ) and ammonium pentazolate ( $(\text{NH}_4)(\text{N}_5)$ ) was predicted using a first-principles evolutionary search of the nitrogen-rich portion of the hydronitrogen binary phase diagram ( $\text{N}_x\text{H}_y$ ,  $x = y$ ) at high pressures [38]. Both crystals would consist of pentazolate ( $\text{N}_5^-$ ) anions and ammonium ( $\text{NH}_4^+$ ) or hydrogen ( $\text{H}^+$ ) cations. These two crystals are predicted to be thermodynamically stable at pressures above 30 GPa for  $(\text{NH}_4)(\text{N}_5)$  and 50 GPa for pentazole  $\text{N}_5\text{H}$ . The chemical transformation of ammonium azide  $\text{NH}_4\text{N}_3$  mixed with dinitrogen ( $\text{N}_2$ ) to ammonium pentazolate ( $(\text{NH}_4)(\text{N}_5)$ ) was predicted to become energetically favorable above 12.5 GPa. To assist in the identification of newly synthesized compounds in future experiments, the Raman spectra of both crystals were calculated, and mode assignments were made as a function of pressure for pressures up to 75 GPa.

After the synthesis of  $(\text{N}_5)_6(\text{H}_3\text{O})_3(\text{NH}_4)_4\text{Cl}$ , in which the cyclo-pentazolate anions were stabilized extensively by hydrogen bridges with  $\text{NH}_4^+$  and  $\text{OH}_3^+$  cations, significant efforts were made to replace these non-energetic cations and the  $\text{Cl}^-$  anion by more energetic cations [39]. The salts made by metathetical syntheses of cyclo-pentazolate salts containing the simple nitrogen-rich cations  $\text{NH}_4^+$ ,  $\text{NH}_3\text{OH}^+$ ,  $\text{N}_2\text{H}_5^+$ ,  $\text{C}(\text{NH}_2)_3^+$ , and  $\text{N}(\text{CH}_3)_4^+$  were characterized by their crystal structures, their vibrational, mass, and multi-nuclear NMR spectra, thermal stability measurements, sensitivity data, and performance calculations. It was shown that the cyclo-pentazolates are more energetic than the corresponding azides but are less thermally stable, decomposing in the range of 333–378 K (80–105 °C). As rocket propellant ingredients, the hydrazinium and hydroxyl ammonium salts were predicted to exceed the performances of RDX and HMX. The crystal structures showed that the cyclo-pentazolate anions were generally stabilized by hydrogen bonds to the cations, except for the  $\text{N}(\text{CH}_3)_4^+$  salt, which also exhibited strong cation– $\pi$  interactions. This difference in anion stabilization was also detectable in the vibrational spectra, which showed for the  $\text{N}(\text{CH}_3)_4^+$  salt a decrease in cyclo- $\text{N}_5^-$  stretching vibrations of about  $20\text{ cm}^{-1}$ .

A debate arose on the possible existence of a neutral  $\text{HN}_5$  species in the pentazolate salt. It was suggested that a few neutral  $\text{HN}_5$  species co-exist in the pentazolate salt, which is consistent with some single-crystal XRD measurements [40].

High yields (>90%) of potassium, ammonium, hydroxylammonium, hydrazinium, aminoguanidinium, diaminoguanidinium, biguanidinium, 3,4-diamino-1,2,4-triazolium, and 3,6,7-triamino-7*H*-[1,2,4]triazolo[3,4-*b*][1,2,4]triazol-2-ium pentazolates were obtained by metathesis reactions of  $\text{AgN}_5$  and the respective chloride salts driven by the precipitation of  $\text{AgCl}$  [41]. All compounds were thoroughly characterized via IR and multi-nuclear NMR ( $^1\text{H}$  and  $^{13}\text{C}$ ) spectroscopy and elemental analysis. The solid-state structural features of the synthesized compounds were also

investigated via single-crystal XRD. The thermal stabilities were investigated by TGA and DSC, and heats of formation and detonation performance were calculated using the Born–Haber energy cycle and the EXPLO5 v6.01 program, respectively. Based on the experimental and theoretical data, biguanidinium pentazolate ( $N = 81.36\%$ ,  $T_d = 397.9\text{ K} = 124.8^\circ\text{C}$ ,  $\Delta H_f = 1362.0\text{ kJ/mol}$ ,  $v_D = 9.257\text{ km/s}$ ,  $P_D = 33.0\text{ GPa}$ ) showed potential as a high-performance energetic material.

The enthalpies of formation of the cyclo-pentazoles and azides of  $\text{NH}_4^+$ ,  $\text{NH}_3\text{OH}^+$ ,  $\text{N}_2\text{H}_5^+$ ,  $\text{C}(\text{NH}_2)_3^+$ , and  $\text{N}(\text{CH}_3)_4^+$  were calculated and, together with experimental densities, used to predict the performances of these salts as explosives and propellants [42]. As explosives, the cyclo- $\text{N}_5^-$  salts outperform the corresponding azides by a significant amount, but as rocket propellants, their performance is slightly inferior. Although the cyclo- $\text{N}_5^-$  salts are building blocks for future energetic materials, their predicted performances are not revolutionary, falling within the range of known CHNO compounds, and they do not approach those expected for polynitrogen cations or neutral polynitrogens. Lattice energy calculations also indicated that the previously reported experimental value of  $114.28 \pm 0.84\text{ kJ/mol}$  for the enthalpy of formation of solid  $\text{NH}_4\text{N}_3$  may need revision.

### 3.3 Six-Membered Ring Homocyclic Hydronitrogen Compounds

The all-nitrogen analogue of cyclohexane,  $\text{N}_6\text{H}_6$ , could be called hexazine or hexaaza-cyclohexane. Forty-eight possible isomers of  $\text{N}_6\text{H}_6$  have been investigated by computational quantum-mechanical modeling [43]. The results showed that the heats of formation of all isomers were positive. The energies and the heats of formation of the ring-shaped isomers were higher than those of the open-chain isomers. Among the ring-shaped isomers, the four-membered ring isomers had the highest heats of formation and the five-membered ring isomers had the lowest. For six-membered ring isomers, only the chair-shaped isomers were predicted to be stable.

## 4 Nitrogen Pentahydride

One has become accustomed to thinking of nitrogen as a trivalent atom when discussing nitrogen hydrides. It would be nice to have a hydronitrogen such as  $\text{NH}_5$  and use it as a rocket propellant, which is not totally improbable since nitrogen is pentavalent in other compounds. Nitrogen pentahydride  $\text{NH}_5$  has been postulated as an intermediate in the reaction of ammonium salts with lithium hydride. Taking speculation about pentavalent nitrogen hydrides one step further,  $\text{H}_2\text{N}-\text{NH}_4$  or even  $\text{H}_4\text{N}-\text{NH}_4$  could be postulated as intermediates in the reaction of hydrazinium(1+) and (2+) salts with lithium hydride.

## 5 Open-Chain Hydronitrogens

The gross formulas of the series of open-chain saturated hydronitrogens follow the general formula  $N_nH_{n+2}$ , where  $n = 1$  gives ammonia and  $n = 2$  gives hydrazine. Hydrazine may also exist (at least temporarily) in the form of isohydrazine  $H-N=NH_3$ . Isohydrazine, predicted by *ab initio* calculations [44], is unlikely to be isolated in measurable amounts because of rapid bimolecular tautomerization:

### 5.1 Diazene

In the singly unsaturated series of hydronitrogens, the gross formula can be represented by the general formula  $N_nH_n$ , including diazene  $N_2H_2$  (also called *diimine* or *diimide*), triazene  $N_3H_3$ , and tetrazene  $N_4H_4$ . Theoretically, the imidogen (imine) radical  $NH$  could also be included in this group, but it is a very unstable compound, though its brief existence in glow discharges has been proved by its emission spectrum. None of these compounds are suitable as rocket propellants, but they may be encountered as intermediates in the decomposition of other hydronitrogens.

Diazene,  $HN=NH$ ,  $N_2H_2$ , CAS RN [3618-05-1], is sometimes also called *diimide* or *diimine*, but the name *diazene* is preferred here. Diazene is a very short-lived species. It has been identified as an intermediate in the decomposition and oxidation of hydrazine. Diazene exists in *cis* [15626-42-3] and *trans* [15626-43-4] forms. It can be stabilized by freezing in a matrix of solid argon or by complexing with transition metal ions. Stable complexes with diazene as a ligand have been described [45, 46]. Such diazene complexes may be intermediates in biological nitrogen fixation. The decomposition of hydrazine in a microwave-induced glow discharge produced a mixture of diazene and ammonia [47]. However, relatively pure diazene can be obtained by pyrolysis of alkali metal tosyl hydrazides [48–50]. The enthalpy of formation of diazene in the gas state is  $+150 \pm 8$  kJ/mol ( $+36 \pm 2$  kcal/mol) [51].

### 5.2 Triazane and Triazene

Triazane,  $H_2N-NH-NH_2$ ,  $N_3H_5$ , CAS RN [14451-01-5], and triazene,  $H_2N-N=NH$ ,  $N_3H_3$ , are not known as stable compounds and may only exist for a short time during the decomposition of other hydronitrogen compounds. Triazane and triazene exist only on paper or in the memories of computers [52, 53]. Predictions were that the *cis* form of triazene would have a specific enthalpy of combustion of 15.2 kJ/g and the *trans* form would have a specific enthalpy of combustion of 14.7 kJ/g. Triazane, if it existed, would have a specific enthalpy of combustion of about 20 kJ/g.

### 5.3 Tetrazane

Tetrazane,  $\text{H}_2\text{N}-\text{NH}-\text{NH}-\text{NH}_2$ ,  $\text{N}_4\text{H}_6$ , CAS RN [6054-69-9], is not known as a stable substance. The properties of tetrazane,  $\text{H}_2\text{N}-\text{NH}-\text{NH}-\text{NH}_2$ , have been predicted from quantum-mechanical calculations [54]. Optimized geometries, vibrational frequencies, conformation energies, heats of formation, and proton affinities for tetrazane were determined using various-level *ab initio* methods.

During the decomposition of hydrazine, it would be easy for two hydrazyl free radicals to combine to form tetrazane:

However, there is no evidence that this actually takes place [55]. Stabilized tetrazane (*n*- $\text{N}_4\text{H}_6$ ) formation from  $\cdot\text{N}_2\text{H}_3 + \cdot\text{N}_2\text{H}_3$  becomes significant only at relatively high pressures and low temperatures because the reverse dissociation back into  $\cdot\text{N}_2\text{H}_3 + \cdot\text{N}_2\text{H}_3$  is the preferred direction.

### 5.4 Pentazenium Salts as $\text{N}_5^+$ Chain Compounds

One of the first  $\text{N}_5^+$  pentazenium salts was  $\text{N}_5^+\text{AsF}_6^-$ , synthesized in 1999 [56, 57]. The assignment of the  $\text{C}_{2v}$ -symmetric structure predicted by calculations was supported by IR and Raman as well as  $^{14}\text{N}$  and  $^{15}\text{N}$  NMR spectroscopic studies of the isotopically labeled product. In inorganic chemistry, a homoleptic chemical compound is a compound in which all bonds and ligands are identical. The five nitrogen atoms are in a linear, V-shaped arrangement, not in a pentazole ring. Similar salts with hexafluoroantimonate [58] or hexafluorostannate [59] as the anion showed surprisingly good thermal stability. One of the  $\text{N}_5^+$  structures was illustrated by a structural model of  $\text{N}_5[\text{Sb}_2\text{F}_{11}]$  that was not only a stick model but also showed the sizes of the atomic (ionic) radii and potential overlaps of the electron clouds [58]. Studying the stability of  $\text{N}_5^+\text{SbF}_6^-$  at higher pressures may aid the discovery of other polynitrogen species. It was found that  $\text{N}_5^+\text{SbF}_6^-$ , when pressurized to 4.5 GPa and heated, was stable to 478 K (205 °C) [60]. The thermal stability of the  $\text{N}_5^+$  cation can be enhanced by pressure.

Now, if one could synthesize  $\text{N}_5^+$  salts with an all-nitrogen anion such as azide  $\text{N}_3^-$  or  $\text{N}_5^-$ , they would make a good source of nitrogen for an airbag inflator and other applications. When investigating the stability of  $\text{N}_5^+\text{N}_5^-$  as an isolated species and in a potential crystal structure, it was predicted that its barriers to loss of  $\text{N}_3^-$  from the  $\text{N}_5^+$  ion and to addition to form  $\text{N}_{10}$  are 105 and 63 kJ/mol (25 and 15 kcal/mol), respectively, and that the barrier to loss of  $\text{N}_2$  from the  $\text{N}_5^-$  ion is 63 kJ/mol (15 kcal/mol) [61].

Attempts to synthesize the all-nitrogen compound  $[\text{N}_5^+][\text{N}_5^-]$  have so far been unsuccessful. It was predicted that neither the  $\text{N}_5^+\text{N}_5^-$  nor the  $\text{N}_5^+\text{N}_3^-$  ion pair are stable

[62]. Both were predicted to spontaneously decompose into  $N_3$  radicals and  $N_2$ . On closer examination, it became increasingly clear that the synthesis of an ionic polynitrogen compound such as  $N_5^+N_5^-$  or  $N_5^+N_3^-$ , consisting of a polynitrogen cation and a polynitrogen anion, is not feasible. This is due to the fact that the first ionization potential of a neutral species is always much higher than its electron affinity. The difference between the two would have to be made up by the lattice energy of the ionic solid.

Unlike  $N_5^+N_5^-$ , for which marginal stability was predicted, the  $N_5^+N_3^-$  ion pair can spontaneously isomerize to azidopentazole, an intermediate with a lower level of energy, which in turn will decompose to molecular dinitrogen [63, 64]. Mixing  $N_5^+SbF_6^-$  and sodium azide  $NaN_3$  did not result in the desired product. Isolation of covalently bonded  $N_8$  from  $N_5^+$  and  $N_3^-$  will be difficult because the most likely product has a decomposition barrier of only 75 kJ/mol (18 kcal/mol). It may not be formed at all, because one of the approach pathways has great potential for mutual neutralization and subsequent fragmentation. Using similar computational techniques, the feasibility of a  $N_3^+N_3^-$  salt has been investigated. It appeared to have sufficient stability to warrant further investigations, but the reaction

did not give the desired product. Attempts were also made [65, 66] to combine the  $N_5^+$  cation with energetic counter-ions such as  $NO_3^-$ ,  $ClO_4^-$ ,  $B(N_3)_4^-$ , and  $P(N_3)_6^-$ .

# Hydrazine

## Hydrazine

Hydrazine, also known as diamide, dinitrogen tetrahydride,  $\text{N}_2\text{H}_4$ ,  $\text{H}_2\text{NNH}_2$ , CAS RN [302-01-2], is the most versatile rocket propellant in that it can be used as a bipropellant fuel, monopropellant, working fluid for electrothermal and arc-jet-augmented thrusters, and as a gas generant. Hydrazine blends with other fuels or water expand the operating temperature range of anhydrous hydrazine under a wide variety of environmental conditions. Hydrazine solutions with dissolved solid oxidizers provide a higher specific impulse than hydrazine by itself. This chapter deals only with hydrazine,  $\text{N}_2\text{H}_4$ , by itself and with hydrazine hydrate,  $\text{N}_2\text{H}_5\text{OH}$ . Hydrazine derivatives like alkylhydrazines will be described in *Encyclopedia of Liquid Fuels*, in three additional chapters: “Alkylhydrazines,” “Dimethylhydrazines,” and “Methylhydrazine.” Hydrazinium salts as solid propellant ingredients were already discussed in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers.” Solid organic hydrazides, useful as coolants and high-nitrogen compounds for gas generators, will be listed in *Encyclopedia of Liquid Fuels*, in the chapter “Amides and Imides.” The current chapter on hydrazine is larger than most other chapters in this book because in many instances, information is provided not only on hydrazine,  $\text{N}_2\text{H}_4$ , itself but also on hydrazine in comparison to its methyl derivatives monomethylhydrazine (MMH) and unsymmetrical dimethylhydrazine (UDMH).

One of the first suggestions for the use of hydrazine as a rocket fuel was in Wernher von Braun’s 1932 book *The Mars Project* (*Das Mars Projekt*, in German) [1]. The launch vehicle would have used white fuming nitric acid (WFNA) and anhydrous hydrazine, certainly a very energetic and storable propellant combination. The first stage of the four-stage launch vehicle would have used 4800 tons of propellants including 1820 tons of hydrazine, the second stage would have used 700 tons of propellants including 266 tons of hydrazine. There was no industrial hydrazine or hydrazine hydrate production in the entire world at the time when that book was written.

It was not anhydrous hydrazine but hydrazine hydrate in a mixture with methanol that was used as the fuel for the world’s first rocket plane, the Me-163B, in combination with hydrogen peroxide as the oxidizer. That was the first time hydrazine (hydrate) got to fly. The fuel requirements for this military war project stimulated hydrazine hydrate production in at least two industrial locations in Germany during World War II (WWII) [2, 3]. Knowledge on how to produce hydrazine hydrate gained during those years served as the starting point and catalyst for the development of a broader-based hydrazine hydrate industry in other countries after WWII, partially helped by hydrazine hydrate production facilities that had been confiscated and dismantled in Germany, shipped out and reassembled by the victorious allied forces in their own countries. Once hydrazine hydrate became available, its usefulness as boiler

feedwater deoxygenating reagent was recognized and led to further expansion of production facilities.

In the post-WWII years, hydrazine, along with hydrazine hydrate and ammonia, was first evaluated as a fuel for hypergolic combinations with chlorine trifluoride or WFNA as oxidizers [4], but it took several years before enough anhydrous hydrazine became available for rocket and liquid gun testing. It took a long time before its true value as a hypergolic storable bipropellant fuel (component) and as a monopropellant was recognized. Early investigators predicted correctly that sustained and technically sound research and development efforts would inevitably lead to the use of hydrazine as an operationally safe and reliable rocket fuel.

## 1 Production of Hydrazine Hydrate and Hydrazine

The first part of this chapter deals just with the production of hydrazine hydrate, often initially in dilute solutions, that cannot be concentrated beyond 64%  $\text{N}_2\text{H}_4$  by simple distillation. Many investigators ignored the fact that a 64%  $\text{N}_2\text{H}_4$  solution is actually a different chemical compound, hydrazine hydrate,  $\text{N}_2\text{H}_5\text{OH}$ , with its own Chemical Abstracts Registry Number CAS RN [7803-57-8], and not concentrated enough to be used as a rocket propellant (unless you dissolve it in another fuel like UDMH or methanol, which has been done). Methods for converting hydrazine hydrate to anhydrous hydrazine will be described at the end of this section.

This chapter provides an update to a summary of methods for the industrial production of hydrazine. Hydrazine (hydrate) is manufactured in large quantities today by reactions that differ markedly from the reaction by which it was first discovered. Curtius discovered hydrazine (hydrazine hydrate, to be precise) in 1887 when he hydrolyzed and simultaneously dimerized diazoacetic acid ethyl ester with a warm, concentrated solution of potassium hydroxide to obtain the dimeric potassium bisdiazooacetate, which is a symmetrical tetrazine derivative [5]. He initially (erroneously) assumed that the acid was a tris-diazoacetic acid. Later investigations showed that both the *3H,6H*-1,2,4,5-tetrazine-3,6-dicarboxylic acid and the more stable *1H,2H*-1,2,4,5-tetrazine-3,6-dicarboxylic acid (with conjugated double bonds) could be formed. When the potassium salt of the dimeric acid was acidified, it yielded an acid that crystallized into yellow plate-shaped crystals. This was distinctly different from the monomeric diazoacetic acid, which would have decomposed in the evolution of nitrogen immediately after liberation. When treating an aqueous solution of the yellow dimeric acid with excess dilute sulfuric acid, the solution became colorless, and the tetrazine derivative was hydrolyzed to hydrazinium(2+) sulfate and oxalic acid

Hydrazinium(2+) sulfate is sparsely soluble in water and precipitated. Additional support for the formation of the dinitrogen base (“diamid”) was proposed by preparing hydrazinium(1+) chloride by the reaction of the newly discovered hydrazinium(2+) sulfate with barium chloride. The reaction based on the hydrolysis of bis-diazoacetic acid could not be scaled up for the industrial production of hydrazinium salts. The industrial production of hydrazine had to wait for Raschig to discover a simpler reaction in 1907, which eventually was named after him:

There are numerous variations of this basic process to protect the formed hydrazine and hydrazine hydrate from further oxidation, but until 50 years ago all industrial processes involved at least partial use of one of these equations (with or without the formation of a ketazine as intermediate). In the meantime, a different process based on ammonia and hydrogen peroxide has gained a larger and still increasing share of the total world production of hydrazine hydrate.

These industrial processes yield not anhydrous hydrazine but a dilute aqueous solution of hydrazine hydrate as the primary product. Most of the hydrazine is used as the hydrate, but several applications, in particular involving its use as a rocket propellant or as an explosive, require anhydrous hydrazine. The various methods for dehydration are discussed in later sections of this chapter. The first chemist to prepare anhydrous hydrazine as a water-free (not quite anhydrous) compound was de Bruyn in 1893.

Numerous alternative methods for the production of hydrazine hydrate have been studied, but so far only one of these methods (the hydrogen peroxide-based process developed by Produits Chimiques Ugine Kuhlmann, or PCUK) is now used on an industrial scale and has overtaken the chlorine-based Raschig and ketazine processes. A shift in the availability of raw materials and energy has made several of these alternate routes for hydrazine hydrate synthesis economically competitive with the Raschig and ketazine processes. More recently, environmental restrictions on the disposal of waste effluents (brine) from hydrazine hydrate manufacturing operations have made the processes with the least waste products more attractive.

Alternate routes to hydrazine include electrolysis, photolysis, radiolysis, and glow discharge ionization of ammonia. A fascinating new synthesis of hydrazine from nitrogen and water was discovered during studies on biotic or abiotic nitrogen fixation with ammonia as the initial target. Hydrazine may be an intermediate of natural nitrogen fixation by bacteria in the root knolls of *Leguminosae* plants. Doing this synthesis *in vitro* would be particularly appealing because nitrogen and water would constitute cheap raw materials on which to base future hydrazine production.

A large portion of information on hydrazine manufacture originates in the patent literature. Although perhaps not all the claims will prove true, patents are included in

this review to show the wide variety of possibilities. A summary of hydrazine manufacturing patents and related literature has been published [6]. Older summaries on hydrazine, landmarks in their own right among the group of hydrazine publications, have been published in book format [7–11], as chapters in conference proceedings [3, 12], or chapters in encyclopedias and monographs [13–21]. None of these sources is nearly as comprehensive as the 2001 second edition of the hydrazine book [22]. A more complete summary of all methods of hydrazine production is presented in that book and need not be repeated here. Here we discuss only a few typical hydrazine-producing reactions that are of interest for hydrazine as a rocket propellant.

The methods for the formation and synthesis of hydrazine can be grouped in the following manner:

- Reduction of compounds containing a nitrogen-to-nitrogen linkage
- Decomposition of ammonia
- Oxidation of ammonia by methods other than those involving the use of hypochlorite
- The Raschig synthesis and related methods.

A rocket engineer would not need to know how to make hydrazine hydrate, except that some of the hydrazine hydrate manufacturing processes introduce unwanted contaminants that are difficult to remove in the dehydration step and are carried over into the anhydrous hydrazine product later used as rocket propellant. These organic contaminants may poison the catalyst in monopropellant thrusters and cause carbide precipitation in refractory alloys at the high operating temperatures of gas generators and electrically augmented monopropellant thrusters.

## 1.1 Natural Occurrence of Hydrazines

Hydrazine may be an intermediate of natural nitrogen fixation by bacteria in the root knolls of *Leguminosae* plants. Methylhydrazine and phenylhydrazine derivatives are found in poisonous and edible mushrooms. The amount of phenylhydrazine eaten by the US population in brown cap mushrooms may equal the amount of hydrazines used as rocket propellants. Many other natural products carry N–N linkages, and their biosynthesis may involve hydrazine intermediates [23].

Anammox bacteria are able to synthesize hydrazine from ammonia and hydroxylamine or ammonia and nitrite in millimolar quantities and play an important role in the nitrogen cycle between oceans, soils, and atmosphere on Earth [24]. Anaerobic ammonium oxidation (anammox) plays a major role in Earth's nitrogen cycle and is used in wastewater treatment. This bacterial process combines nitrite and ammonium to form dinitrogen ( $N_2$ ) gas and has been estimated to synthesize up to 50% of the dinitrogen gas emitted into our atmosphere from the oceans. An optimum ratio of ammonia and nitrite in an anammox bioreactor feed will result in a distinct yield of hydrazine

when samples are taken at different times [25]. The optimal ratio of ammonium and nitrite is essential for the successful operation of the subsequent anammox process. A partial nitrification experiment using an upflow air-lift reactor was carried out to determine operational parameters for achieving the optimal ratio of ammonium to nitrite by feeding supernatant of anaerobic digester effluent, high-nitrogen-containing rejection water to the reactor. Hydrazine concentration increased during partial nitrification by 60–130%. Surprisingly, the anammox process relies on the highly unusual, extremely reactive intermediate hydrazine. So far, the exact enzymatic mechanism by which hydrazine is synthesized is unknown [26], but investigators have begun to shed light on this multi-step biological process [27]. Hydrazine synthase, a gene in anammox bacteria, is the enzyme that achieves this reaction. One day in the distant future it will be possible to synthesize hydrazine in quantity by a bacterial process similar to the fermentation of sugar to make ethanol.

Hydrazine synthase, encoded by the *hzsABC* gene cluster, is a unique and irreplaceable enzyme for the anammox reaction in many bacteria. This gene is widely used as a functional gene biomarker to retrieve the diversity, abundance, and activity of anammox bacteria in different ecological niches. The genome of anammox bacteria contains two identical copies of the *hzsABC* gene cluster [28].

Bacteria can digest isotope-labeled lysine and glycine and form a compound in which the two amino acids are linked by a hydrazine bridge [29]. L-lysine and glycine units were connected via a hydrazine linkage. Acid hydrolysis of the dipeptide gave hydrazinium salts and hydrazinoacetic acid. It may be possible to manipulate genes in bacteria such that hydrazine becomes a major product of bacteria metabolism. Thus, some bacteria can thrive on hydrazine as a nutrient, and other bacteria incorporate —NH—NH— compounds in their digestive output.

There is a potential in the future for producing hydrazine via microbial conversion of NO and ammonium in an industrial process [30], much like ethanol is made by the fermentation of sugars.

The clouds on Jupiter consist of ammonia, and some hydrazine may form in these clouds and rain or snow from ammonia clouds under the sunlight UV and cosmic radiation conditions of Jupiter [31–36]. The discrepancy between the Jovian albedo in the IR and UV may still be an open question. However, if condensation nuclei were present to such an extent that  $N_2H_4$  condensed before it reacted or photodissociated, then an explanation of the discrepancy might be possible [37]. There would be a stationary hydrazine concentration because hydrazine decomposes just as fast as it forms under the conditions of the upper Jovian atmosphere (except when it condenses and rains down into the lower atmosphere, where it is protected from radiation). Even under the most conservative estimates, the amount of hydrazine present in the Jovian atmosphere at any one time could equal the mass of Earth's oceans. In the presence of both ammonia and methane, methylamines and other organics might form as well. Ammonia, amines, and hydrazine might form hydrosulfides in the presence of hydrogen sulfide. The hydrosulfide salts might condense and precipitate, but they also easily dissociate

and sublime once they enter warmer regions in the atmosphere. The maximum hydrazine ice production rate was estimated to be about  $6.9 \times 10^{10}$  molecules  $\text{cm}^{-2} \text{s}^{-1} = 1.3 \text{ mg m}^{-2}$  Jovian day<sup>-1</sup> [38].

From an analysis of the GALILEO and CASSINI Infrared Imaging Spectrometer data, it was reported that spectrally identifiable ammonia clouds cover less than 1% of Jupiter. Yet ground-based, satellite, and spacecraft observations show that clouds exist everywhere on Jupiter. Thermochemical models also predict that Jupiter must be covered with clouds, with the top layer made up of ammonia and/or hydrazine ice [39]. A substantial amount of haze material can deposit on the upper cloud layer of Jupiter, possibly enough to mask (disperse) its spectral signature.

Observations by VOYAGER, CASSINI, and NEW HORIZONS fly-bys and GALILEO and JUNO planetary probes in orbits around Jupiter have confirmed the presence of white clouds, which could be a hydrazine haze [40]. Ammonia is by far the dominant cause of microwave opacity in Jupiter's molecular atmosphere, surpassing water vapor by more than an order of magnitude. Ammonia and hydrazine IR spectra overlap in the N—H region. If there are aqueous ammonia clouds on Jupiter, then aqueous hydrazine (i.e., hydrazine hydrate) clouds are likely to condense before ammonia-water clouds do.

The hydrazine stratospheric haze would be expected between 40 and 20 mbar centered at 30 mbar with a particle volume density of about 4 particle/ $\text{cm}^3$ . Graphs derived from JUNO 2016 based on an analysis of the spectral range between 2.4 and 3  $\mu\text{m}$  showed maps of the hydrazine column particle density and peak altitude in areas of oval white spots in the southern hemisphere [41].

Hydrazine is a known byproduct of chloramination in the disinfection of drinking water. Trace amounts of hydrazine have been reported in chloraminated drinking water samples.

## 1.2 Production of Hydrazine from Nitrogen and Hydrogen

The direct synthesis of hydrazine from the elements has been attempted by numerous investigators using a variety of methods. They attempted to stimulate the otherwise inert nitrogen to enter into bonding with hydrogen. At best, however, the result was ammonia. Traces of hydrazine were detected in some cases, but the yield was in the fractional percents and did not warrant commercial exploitation of the new synthesis. The nitrogen/hydrogen mixture has been stimulated by high pressure, glow discharge, RF plasma discharge,  $\beta$  radiation, or  $\gamma$  radiation in unsuccessful attempts to produce hydrazine more economically than with the current aqueous processes followed by the dehydration of hydrazine hydrate. It was suspected that under the conditions of industrial ammonia synthesis from the elements, a small fraction of hydrazine might form under non-equilibrium conditions but would most likely decompose during cooling of the reaction mixture. Nitrogen/hydrogen mixtures were flowed over ammonia

catalysts at high space velocities and short contact time. The condensate contained a trace of a reducing compound (hydrazine??) besides ammonia; however, hydrazine was not positively identified. Thus, if hydrazine could be obtained economically as a byproduct of ammonia synthesis, even a hydrazine yield of a fraction of a percent of all ammonia formed in the same process would be enough to meet current world demand for hydrazine.  $\text{Co}_3\text{Mo}_3\text{N}$  is one of the most active catalysts for ammonia synthesis; however, little is known about the atomistic details of  $\text{N}_2$  adsorption and activation. Density functional theory (DFT) calculations have been applied to elucidate the associative mechanism for hydrazine and ammonia synthesis in the gas phase and hydrazine formation on  $\text{Co}_3\text{Mo}_3\text{N}$  [42].

Compressing mixtures of nitrogen and hydrogen at very high pressures (as they might exist in the interior of gaseous giant planets) is predicted to form ammonia and hydrazine and some hitherto unknown compounds, such as pentazole or ammonium pentazolate. Some of these hypothetical hydronitrogens are discussed in *Encyclopedia of Liquid Fuels*, in the chapter “Hydronitrogen Compounds.”

### 1.3 Production of Hydrazine from Ammonia

The difficult task of arranging two nitrogen and four hydrogen atoms in proper order to form hydrazine gets a head start if ammonia (instead of a random mixture of nitrogen and hydrogen as in the preceding section) is used initially. There are essentially two different ways to knock off one hydrogen from ammonia and have the remainder combine to form hydrazine: by ammonia decomposition or by chemical oxidation. Ammonia decomposition according to

tends not to be very selective and frequently proceeds all the way to nitrogen and hydrogen without intermediate formation of hydrazine. One must quench the reaction mixture at the right moment. Methods of ammonia decomposition include pyrolysis, photolysis,  $\alpha$ -radiolysis,  $\gamma$ -radiolysis, glow discharge, electric arc plasma, and utilization of radioactive decay recoil energy. Numerous publications deal with the UV photolysis of ammonia that results in hydrazine formation. Not all of those need to be referenced here. These reactions are summarized in detail in [43]. The discussion of hydrazine made by the photolysis or radiolysis of ammonia would constitute a major chapter by itself. The clouds on Jupiter consist of ammonia, and it is possible that some hydrazine can form in ammonia clouds under the conditions of Jupiter with cosmic radiation or UV light from the Sun. More energetic radiation, like  $\gamma$  radiation from a  $^{60}\text{Co}$  source, will convert ammonia to hydrazine or hydrogen azide. Glow discharges can work with electrodes immersed in plasma or with electrodeless discharges in an intense RF field. The cost of electricity are very high and the yields of hydrazine very low.

Chemical oxidation, on the other hand, can be better controlled and under suitable conditions will lead to better conversion of ammonia to hydrazine. In many cases, ammonia derivatives (e.g., urea) are used in place of ammonia, or the hydrazine is protected from further interaction with the oxidizer by forming an azine (Bayer process). Under current market and raw material conditions, the chemical oxidation of ammonia, as opposed to the pyrolysis or photolysis of ammonia, is the most economical method for manufacturing hydrazine on a large industrial scale. The oxidant can be chlorine (hypochlorite) or hydrogen peroxide. Why not use air? It would be tempting to write an equation for the formation of hydrazine from ammonia by oxidation with air,

but under real-life conditions the hydrazine formed would be quickly destroyed by oxidation before any more ammonia could be reacted.

### 1.3.1 Production of Hydrazine by Chemical Oxidation of Ammonia

All hydrazine syntheses discussed in the previous section on ammonia decomposition had one scheme in common, the generation and recombination of amidogen  $\cdot\text{NH}_2$  free radicals. In the case of ammonia electrolysis, one may speak of an anodic oxidation. The technically more important processes for the production of hydrazine from ammonia involve a chemical oxidation, usually in aqueous solution and only yielding hydrazine hydrate instead of hydrazine. Throughout the following discussions, when the word *hydrazine* is used in reference to aqueous solutions, it should be understood that the real species in aqueous solution is hydrazine hydrate,  $\text{N}_2\text{H}_5\text{OH}$ , and *not* free hydrazine,  $\text{N}_2\text{H}_4$ . The oxidizing agent in most cases is chlorine or hypochlorite. The oxidation may proceed through a well-defined intermediate, such as chloramine, and would be conducted stepwise.

#### 1.3.1.1 Production of Hydrazine by Raschig Process

The most important method for hydrazine preparation was for a long time the Raschig process. The explanation of how the Raschig process works usually goes as follows. The initial reaction of sodium hypochlorite with one molecule ammonia forms chloramine:

This reaction takes place very rapidly. Chloramine  $\text{ClNH}_2$  is sometimes also called monochloramine in order to differentiate it from dichloramine  $\text{Cl}_2\text{NH}$  (dichloroamine).

Chloramine in alkaline solution is not infinitely stable at temperatures above 268 K ( $-5^\circ\text{C}$ ). If it did not react with another molecule of ammonia in time, it

might hydrolyze and decompose to nitrogen, hydrogen chloride, and water. The pH for chloramine synthesis and subsequent hydrazine synthesis must be kept in a certain range for optimum yields. At values below 8.5, the unstable more highly chlorinated byproducts dichloramine and nitrogen trichloride may lead to accidental explosions. If the pH increases above 11, the preceding equation reverses itself, and the chloramine hydrolyzes. The best chloramine yields are obtained in the presence of an excess of ammonia, but the higher pH limits the life of the resulting solutions, and the half-life at 273 K is on the order of 10–15 h. The reaction of chloramine with ammonia forms hydrazine:

Or, in the presence of an excess of ammonia and alkali [44],

It has been found advantageous to separate hydrazine production into two steps: reaction of hypochlorite with a moderate excess of ammonia at low temperatures (forming chloramine as main product) followed by sudden reaction with a larger excess of ammonia at 400 K. This two-step reaction is reflected in the flow diagram of an industrial process (Figure 1).

In aqueous solutions this reaction produces a dilute solution of hydrazine hydrate (not hydrazine). Chloramine solutions find use in the synthesis of other hydrazines (MMH, UDMH) reacting chloramine with alkylamines instead of ammonia.

Chloramine is also used in the disinfection of drinking water. Active chlorine in the form of chloramine tends to last longer and will not evaporate as quickly as free dichlorine. The use of chloramine instead of free chlorine for drinking water treatment reduces the formation of toxic trihaloalkanes (chloroform) but may lead to traces of hydrazine among other byproducts of drinking water disinfection [45–47].

### 1.3.1.2 Separation of Hydrazine Hydrate and Water

One of the main disadvantages of the Raschig and other hydrazine processes is the low concentration of hydrazine, requiring repeated distillation or intermediate precipitation as hydrazinium sulfate to obtain a product with an acceptable hydrazine concentration. Numerous methods have thus been developed and patented to recover the hydrazine from reaction liquor. The economy of hydrazine production depends heavily on the method of hydrazine recovery. Solutions of hydrazine in water with less than 64%  $\text{N}_2\text{H}_4$  are actually solutions of hydrazine hydrate in water.

Most hydrazine hydrate synthesis processes produce dilute solutions containing less than 10%  $\text{N}_2\text{H}_4$ . The solutions must be concentrated by distillation or other separation process to achieve 64% in the first step and eventually 99–100%  $\text{N}_2\text{H}_4$  before it can be used as a rocket propellant.

**Figure 1:** Raschig process and dehydration plant design. (Reproduced from [22]. Courtesy of Wiley-Interscience.)

### 1.3.1.3 Separation of Hydrazine Hydrate and Water by Pervaporation

Pervaporation can separate liquids of different polarity and molecular structure due to different levels of permeability. The permeate, once it has traveled through the membrane, is removed by evaporation instead of being accepted into another liquid phase, as in osmosis.

Ethylcellulose membranes have been selected for the separation of hydrazine and MMH solutions by pervaporation based on an extensive study of the overall mass transfer resistance experienced by permeants [48]. Resistance values were quantitatively estimated by changing the membrane thickness and calculating the corresponding flux. Because of its lower sorption and fewer interactions, the membrane showed the least amount of desorption resistance toward water, and so it is permselective with respect to water. The results of pervaporation selectivity obtained in the separation of water/hydrazine and water/MMH mixtures at azeotropic compositions have been correlated. Higher sorption of MMH and hydrazine did not result in preferential separation despite lower membrane resistance. Experimental results clearly showed that desorption resistance and diffusivity predominated over the corresponding solubilities. To confirm the reasons for these phenomena,

Fourier transform infrared (FTIR) spectra and differential scanning calorimetry (DSC) thermograms of membranes soaked in pure hydrazine, MMH, water, or hydrazine hydrate were compared.

### 1.3.2 Production of Hydrazine by Sisler Process

Although the Sisler process has never advanced to the level of industrial usage, the concept is mentioned here because it skips the stage of hydrazine hydrate and leads directly to anhydrous hydrazine.

### 1.3.3 Production of Hydrazine by Ketazine Process

The yield of hydrazine in the Raschig processes is limited by the undesirable reaction of hydrazine with chloramine. The required large ammonia excess leads to bulky equipment and low hydrazine concentrations in the aqueous product solution. The removal of water and the concentration of the dilute hydrazine solution require substantial amounts of energy. Some of the disadvantages of the Raschig process are overcome by the ketazine process, in which hydrazine is reacted with carbonyl compounds immediately after its formation and so is protected from further reaction. Other disadvantages of either of the two aforementioned processes are avoided by the PCUK process discussed subsequently. The most commonly used carbonyl compound is acetone, which forms a ketazine, acetone azine  $(\text{CH}_3)_2\text{C}=\text{N}=\text{N}=\text{C}(\text{CH}_3)_2$ , or a hydrazone, acetone hydrazone  $(\text{CH}_3)_2\text{C}=\text{N}-\text{NH}_2$ . Typically, a molar ratio of ketone : hydrazine above 2 is used to obtain the ketazine. The reaction can be carried out at ambient pressure and does not require heating of the reaction mixture.

The main advantage of the ketazine process is that the diaziridine or ketazine is not susceptible to further oxidation by chloramine unlike hydrazine. The energy required for distillation is significantly less than in the Raschig process. Less ammonia excess is used, and ammonia is not as soluble in the ketone/water mixture as in water. A process flow schematic of the ketazine process is shown in Figure 2.

The high organic content of the ketazine process product has restricted the use of ketazine-produced hydrazine hydrate for applications where high-purity hydrazine is required, as in monopropellant rocket engines. Vacuum distillation was attempted for the removal of organics.

The hydrazine hydrate resulting from ketazine hydrolysis contains large amounts of organic contaminants [corresponding to 500 to 1500 ppm total organic carbon (TOC)]. The list of contaminants found in ketazine product and ketazine wastewater is several pages long. Compounds found include various alcohols, ketones, amines, amides, oximes, pyrazines, pyrazoles, pyrazolines, pyrrols, pyridines, pyridazines, triazoles, and even imidazole. Of these, the amides are the least volatile and may require a separate removal step. Distillation of a ketazine-process product in a 40-tray column that had a stream of hydrazinium salt or other salt solution fed to the tenth tray from the top and feed (100% hydrazine hydrate) fed to the tenth tray from the

**Figure 2:** Bayer ketazine process flow chart. (Reproduced from [22]. Courtesy of Wiley-Interscience.)

bottom was shown to reduce the TOC from 720 to 90 ppm following a second, simple hydrazine hydrate distillation process at a reduced pressure of 9.3 kPa (70 mm Hg) [49].

### 1.3.4 Production of Hydrazine Hydrate by PCUK Process

The French process using acyl peroxides for oxidizing ammonia in the presence of a ketone to synthesize hydrazine hydrate deserves special mention because it may be conducted as a cyclic process where one of the raw materials can be recovered. Ammonia and hydrogen peroxide are consumed in the process. The synthesis cycle is shown here, and a process flow schematic is shown in Figure 3.

The process was announced in initial press releases by Produits Chimiques Ugine Kuhlmann (PCUK, later Atofina S.A., now Arkema) and has found widespread application. Most new plant constructions during the past two decades were based on

**Figure 3:** PCUK/Atofina/Arkema peroxide process flow chart. (Reproduced from [22]. Courtesy of Wiley-Interscience.)

the PCUK/Atofina/Arkema process. The PCUK/Atofina plant at Lannemezan in France was the first of its kind. It began operation in October 1981. The process works with either methylethylketone or acetone. The hydrazine hydrate product contains varying amounts of ketone-derived organics as contaminants, many of a heterocyclic nature with boiling points like that of hydrazine hydrate, such that they cannot be removed by simple distillation. While these organics may not interfere with other industrial uses of hydrazine hydrate, they would cause problems if ketazine-derived hydrazine hydrate were dehydrated to make anhydrous hydrazine, and the contaminants would carry over into the anhydrous hydrazine, which then could not be used as a monopropellant.

#### 1.4 Preparation of Hydrazine Free Base from Salts

The first method for the industrial production of hydrazine hydrate, before the distillation methods were perfected, used the reaction of the relatively insoluble, easily crystallized hydrazinium(2+) sulfate with aqueous alkali to liberate the free base and distill it once [50].

Anhydrous hydrazine can be obtained by a dry-state reaction between hydrazinium(2+) chloride and sodium hydroxide in the absence of water. The reaction between the two salts starts by slowly heating the mixture under vacuum in a flask connected to a cold trap and immediately removing the heat source as soon as the reaction starts [51]. This method can also be used for the preparation of deuterated hydrazine,  $N_2D_4$ .

### 1.5 Dehydration of Hydrazine Hydrate

A significant fraction of hydrazine is used as hydrazine hydrate, but its application as rocket propellant requires anhydrous hydrazine. In an attempt to obtain hydrazine with more than 64%  $N_2H_4$ , the last water is not easily removed from the hydrazine hydrate commonly used as a starting material. Hydrazine hydrate cannot be dehydrated by simple distillation. The water can be removed by chemical reaction followed by distillation or by azeotropic distillation with an auxiliary fluid. The best method of separation is by distillation, which is a continuous, not batch, process, but special precautions are required to prevent explosive decomposition of hydrazine vapors in the still.

Historically, anhydrous hydrazine in the US has always been made from Raschig-process hydrazine hydrate. Nowadays it is much cheaper to make hydrazine hydrate by the Bayer ketazine or Arkema peroxide process. Anhydrous hydrazine made by the aniline dehydration process was discontinued in 2004. A different process was used until 2013 at Lonza-Arch to make ultrapure hydrazine from hydrazine hydrate. The hydrazine hydrate for it was initially made by the traditional Raschig process, which is no longer in operation. At one time, managers decided it would be cheaper to use hydrazine hydrate that came from a ketazine or peroxide process, not realizing that the resulting anhydrous hydrazine would not be acceptable for long-duration, high investment space missions requiring ultrapure hydrazine in monopropellant and electrically augmented thrusters. Anhydrous hydrazine made from ketazine HH100 is not acceptable for electrothermal thrusters owing to its high content of organic contaminants. The reason for this is the carryover of organic contaminants with similar boiling points from the ketazine process into the product hydrazine. What is still missing is a good and thorough study of typical organic contaminants in ketazine-process hydrazine hydrate. Unpublished information indicates that there are several dozen organic contaminants in ketazine hydrazine hydrate, many of which are heterocyclic compounds with boiling points similar to those of hydrazine hydrate and hydrazine. There may be methods to purify ketazine hydrazine hydrate (100%  $N_2H_5OH = HH100$ ) and remove all organics before it is processed into anhydrous hydrazine. A two-step fractionated distillation, the second step performed under reduced pressure, with a nitrogen purge, can produce anhydrous hydrazine without the aid of an auxiliary fluid [52, 53].

tion **D** (5.7%  $\text{N}_2\text{H}_4$ , 24.3%  $\text{H}_2\text{O}$ , 70%  $\text{NaOH}$ ) and 17.6 parts of an upper, hydrazine-rich layer of the composition **E** (92.7%  $\text{N}_2\text{H}_4$ , 4.4%  $\text{H}_2\text{O}$ , 2.9%  $\text{NaOH}$ ). A similar composition is obtained by mixing equal amounts of sodium hydroxide and 100% hydrazine hydrate (point **C'**). The upper layer contains 78% of the hydrazine in the total system. The two layers are usually separated while still hot, and various methods for the purification and further concentration of the upper layer have been proposed. These involve reaction with barium oxide or distillation. The use of sodium hydroxide in excess of concentration at point **C** or **C'** is not recommended, because this will result in a third phase, solid sodium hydroxide, occurring in region **III**. The example cited in [56] used 500 parts of a 54.5% aqueous solution of hydrazine, 523 parts of sodium hydroxide, and 200 parts of an inert paraffinic hydrocarbon boiling between 394 and 416 K (121 and 143 °C) as a blanketing fluid. *n*-Heptane has been used for this purpose. The hydrocarbon is not miscible with hydrazine and can easily be separated from the distillate by decantation. The purpose of adding the hydrocarbon is to dilute the hydrazine vapor below the detonable concentration.

The early Brauer *Handbook of Preparative Inorganic Chemistry* (in German) method should no longer be used and should NOT be scaled up to the 1-kg level because of the risk of explosion [57]. This hazardous procedure was removed from later editions of the book. Another investigation of different  $\text{NaOH}$  dehydration methods is described in [58].

The water-rich  $\text{NaOH}/\text{H}_2\text{O}$  phase that is obtained when adding at least one mol of  $\text{NaOH}$  for each mol of  $\text{H}_2\text{O}$  to be removed can later be used to make sodium hypochlorite for making more hydrazine by the Raschig process [59]. Besides solid sodium hydroxide in a batch process, concentrated aqueous sodium hydroxide solution can be used as a desiccant when exposed to a countercurrent stream of hydrazine hydrate vapor in a continuous process [60, 61]. The caustic solution must be very, very concentrated, approximately >50 mol-%  $\text{NaOH}$ . Downstream, the water is driven off from the exhausted desiccant by heating, thereby concentrating the solution and making it ready for recycling.

Distillation of hydrazine in the presence of alkali can be avoided by extracting the hydrazine in the upper phase of the  $\text{NaOH}/\text{N}_2\text{H}_4/\text{H}_2\text{O}$  system with aniline, drying with solid  $\text{NaOH}$ , and distilling the 7% hydrazine/93% aniline extract under anhydrous low-pressure conditions [62, 63]. This method will give a product with 97.1%  $\text{N}_2\text{H}_4$ .

A detailed description of the operational details of the sodium hydroxide/hydrazine/water phase separation process is given in a French patent [64]. The upper phase can be purified either by distillation, as described in several references, or by a combination of ion exchange and zone refining.

The need to reflux the mixture prior to phase separation has been questioned. Some authors distilled the entire mixture without prior phase separation. In one test series, 25.3 g hydrazine hydrate (64%  $\text{N}_2\text{H}_4$ ) and 24.7 g reagent-grade  $\text{NaOH}$  were heated in an oil bath to 351–368 K (78–95 °C) and distilled at 21 kPa (160 mm Hg)

through a glass distillation column [column head temperature 342–349 K (69–76 °C)] with a slow purge of nitrogen [65]. The hydrazine assay was 98.6 to 99.5%  $\text{N}_2\text{H}_4$ , and the yield was 82 to 91%.

More detailed data on the phase boundaries in the ternary  $\text{NaOH}/\text{NH}_3/\text{H}_2\text{O}$  system and the quaternary system  $\text{NaOH}/\text{N}_2\text{H}_4/\text{NH}_3/\text{H}_2\text{O}$ , which are useful for optimizing semi-industrial batch processes for making anhydrous hydrazine, have become available [66–68]. The sodium hydroxide and water content in the upper phase can be reduced by adding an excess of ammonia under pressure. The  $\text{NaOH}/\text{NH}_3/\text{H}_2\text{O}$  system has immiscible phase boundaries like the  $\text{NaOH}/\text{N}_2\text{H}_4/\text{H}_2\text{O}$  system, but with less  $\text{NaOH}$  in the upper phase. The quaternary system  $\text{NaOH}/\text{N}_2\text{H}_4/\text{NH}_3/\text{H}_2\text{O}$  was studied to obtain the optimum demixing temperature and minimize the  $\text{NaOH}$  content of the upper phase. The process is based on the presence of a miscibility gap under pressure in the solid/liquid/liquid  $\text{NaOH}/\text{NH}_3/\text{H}_2\text{O}$  ternary system. In the new process, ammonia was no longer evacuated by stripping (as in the traditional process) but retained in the demixing step, in order to apply its solvent effect to the  $\text{N}_2\text{H}_4$  extraction. After separating the two phases, it is then easy to drive off the excess ammonia and recycle it. The upper phase can be purified by fractionated crystallization instead of distillation, thereby avoiding the most dangerous step of the older methods.

In the early 1990s, Japan developed the capability to produce 400 kg anhydrous hydrazine/month through a sodium hydroxide process starting with commercial-grade hydrazine hydrate and using toluene as a blanketing fluid during distillation [69]. This hydrazine was used for the H-II second-stage roll control system. This was a two-step distillation that produced 94%  $\text{N}_2\text{H}_4$  as an intermediate product. The domestic Japanese specification allowed 0.5% toluene and 0.1% sodium to remain in the product (comparable to the 0.5% aniline in US MIL-SPEC monopropellant-grade hydrazine), but advertised product contained only 0.002% toluene and 0.001% sodium.

The process once used by Lonza-Arch (former Olin Chemicals, now Arxada) in the United States for making a product called *Ultrapure*® Hydrazine is assumed to be a distillation process similar to that described in a series of Olin patents [70, 71]. Those patents describe the preparation of high-purity hydrazine from hydrazine hydrate and sodium hydroxide in a batch process where the product is distilled at reduced pressure ( $<8 \text{ kPa} = <60 \text{ mm Hg}$ ) in a fractionation column directly from a sump containing the mixture of hydrazine hydrate and sodium hydroxide. The patents do not indicate whether or not the two liquid phases are separated prior to distillation. In one of the variants, less than 0.5 mol sodium hydroxide per mol of water are used, which may be insufficient to achieve phase separation. The UltraPure® hydrazine was produced in commercial quantities and supplied to the US Air Force (USAF) and the aerospace industry for use in satellites, space probes, and launch vehicles for several decades until the supply of Raschig HH100 was exhausted and an inferior-quality AH was made from a ketazine HH100.

Removing water by adding sodium hydroxide is not truly a chemical reaction. Some of the dehydrating reactions use chemical water scavengers, where the water is consumed in irreversible reactions. Sodium amide, calcium hydride, calcium carbide, calcium oxide, or barium oxide were also used to remove water from hydrazine hydrate or to remove the last traces of water from hydrazine that had been mostly, but not completely, dehydrated by other methods.

### 1.5.2 Dehydration by Distillation with Azeotrope-Forming Auxiliary Fluids

The water that is firmly bound as hydrazine hydrate in  $\text{N}_2\text{H}_5\text{OH}$  can be removed by distillation with azeotrope-forming auxiliary (entrainer) fluids. The fluid most frequently used for this purpose was aniline. Aniline was ideally suited for this purpose, and its use is described in several patents and publications [72–76]. Other fluids evaluated for this purpose, but found to be less suitable, included lower alkyl monoethers of diethylene glycol [77], *n*-propanol or 2-propanol, phenol, cresol, 1,2,6-hexanetriol, glycol, pyridine, *n*-hexylamine, *n*-hexanol, phenol, xylidine, and aromatic hydrocarbons like benzene, toluene, or xylene. Any distillation process involving anhydrous hydrazine, be it with an entrainer fluid or not, is potentially hazardous since hydrazine vapor can explode over a wide range of partial pressures. When operating a continuous distillation process, the aniline reflux ratio can be adjusted to achieve an optimum dehydration and to minimize the overall energy consumption. Depending on the reflux ratio, up to 0.5% aniline may remain in the hydrazine product, which is not very desirable. Usually, this small amount of aniline does not interfere with some of the intended uses of anhydrous hydrazine, such as in bipropellant applications, where it is mostly mixed with UDMH anyway. However, for monopropellant applications, even ppm quantities of aniline have been shown to have adverse effects on ignition delay with catalysts. One way to lower the aniline content is to extract it with a low-boiling-point hydrocarbon, such as benzene or butane. The other method for aniline removal is fractionated freezing (Section 1.6.1).

The hydrazine book [22] contains more details on the use of aniline for the dehydration of hydrazine hydrate, but because this process has now been abandoned and is only of historical interest, this information is not repeated here.

### 1.5.3 Removal of Water by Two-Phase Liquid-Liquid Extraction

Attempts have been made to split hydrazine hydrate into water and hydrazine by two-phase liquid-liquid extraction, but these processes have never been used on an industrial scale. Starting with the very dilute solution of hydrazine hydrate in water as it emerges from the Raschig process, it is possible to end up with pure anhydrous hydrazine by a combination of distillation, two-phase extraction, and fractionated crystallization processes [78].

#### 1.5.4 Removal of Water by Membrane Separation

It would be quite desirable to find a process by which water can be removed from dilute solutions of hydrazine (or even from hydrazine hydrate) by selective permeation through semi-permeable membranes. The other side of the membrane could be wet and flushed by a liquid that is easily separated from anhydrous hydrazine by simple distillation, or the other side could be dry with a purge gas, in which case this process is called pervaporation [79–84]. Pervaporation for concentrating process liquors has been tested for hydrazine as well as MMH and UDMH. A variety of membrane materials have been tested for this purpose, including ethyl cellulose [85–87]. It is not known whether pervaporation is already used in any of the industrial production plants for these three rocket fuels.

The pervaporation of hydrazine can also be accomplished in high-surface-area hollow fiber modules like those used for desalination [88]. Chitosan, ceramic, and zeolite membranes can be used for the dehydration of hydrazine fuels by pervaporation [89]. Molecular sieve membranes have selective permeability for molecules of a certain size and polarity [90].

Because the pore openings in molecular sieves allow only the passage of small molecules, this method can be used for the purification of hydrazine in aqueous solutions. It is not known whether the membrane would also work for the purification of anhydrous hydrazine.

Membrane distillation is an alternative but safe process for the dehydration of hydrazine hydrate since water can be vaporized thermally through a porous hydrophobic membrane. The proper selection of membrane polymer is an important pre-condition due to the high corrosivity of hydrazine. A solvent-resistant, hydrophobic, and mechanically robust microporous polystyrene membrane was prepared on a macroporous polyester fabric support using a phase inversion technique and crosslinked with tetraethyl orthosilicate for membrane distillation dehydration of hydrazine hydrate [91]. SEM and FTIR studies were performed to study membrane morphology and intermolecular interactions. Microporous polystyrene membranes were able to separate feed mixture containing 50 mass-% hydrazine by exhibiting a reasonable water flux of  $5.03 \text{ kg m}^{-2} \text{ h}^{-1}$ , with water concentration in permeate being 97.18% at 75 mm Hg downstream vacuum. Similar membranes were also used for the distillation of MMH or UDMH.

### 1.6 Purification of Anhydrous Hydrazine

Contaminants can be removed from anhydrous hydrazine by various methods. Hydrazine contaminated by UDMH had to be sparged with pure nitrogen gas for several days in an effort to remove the more volatile contaminant. Contaminants with boiling points like that of hydrazine are more difficult to remove.

### 1.6.1 Purification of Anhydrous Hydrazine by Freeze-Thaw Process

An efficient method for aniline and water removal had been developed by Martin Marietta Aerospace Corporation, Denver Division [92]. The requirement for high-purity, aniline-free hydrazine came about as a result of the Viking spacecraft mission to Mars in the 1970s. This spacecraft required a propellant free from organic contaminants for its landing rocket engines using hydrazine monopropellant. Organic contaminants, in particular hydrogen cyanide, would have interfered with the biology/life-detection experiments. As a result of this space program, hydrazine purification technology received a new impetus, and many other programs have benefited from the availability of what was initially called Viking Grade hydrazine.

The process used by Martin Marietta for several decades consisted of two large trays, which could be operated independently of each other and together held 272 kg (600 lb) of hydrazine. Refrigerant was fed to the purification tray heat exchanger coil at a temperature of  $262.6 \pm 1$  K ( $13 \pm 2$  °F). The refrigerant flow rate was adjusted such that the outlet-inlet temperature difference was only 2 °C. The objective was to freeze the contents of the tray slowly with gentle rocking, allowing the pure crystals to settle and the contaminants to accumulate in the supernatant fluid, which was later decanted. The supernatant fluid of the first cycle was usually discarded, but low-melting fractions from subsequent cycles could be collected and worked up to give an additional crop of hydrazine that could be recycled. After three to four freeze-thaw cycles, the aniline content was lowered to less than 5% of the aniline content in the starting process feed. The carbon content was lowered from approximately 7000 ppm to less than 20 ppm. Special precautions were necessary to prevent atmospheric carbon dioxide contamination of the purified product during transfer, sampling, and preparation for shipment.

A few years after Martin Marietta closed the freeze-thaw purification plant in Denver, Entwicklungsring Nord, Bremen, Germany, later a division of Messerschmitt-Bölkow-Blohm (MBB-ERNO, later a division of Astrium, now part of Ariane Group) installed a more sophisticated freeze-thaw purification plant under contract from the European Space Agency (ESA) in Trauen, Germany [93]. This plant utilized a modification of a commercially available crystallization apparatus that was previously used for other (pharmaceutical, organic fine chemical, natural product purification) applications. The plant was designed to be able to operate on three different types of feedstock:

1. Standard-grade hydrazine
2. Monopropellant-grade hydrazine
3. A 92%  $\text{N}_2\text{H}_4$  sodium-rich concentrate that is typically obtained from hydrazine hydrate by addition of sodium hydroxide and phase separation.

The plant was expected to mostly operate on monopropellant-grade hydrazine feedstock. It differed from the Martin Marietta batch-mode rocking-tray-decantation pro-

cess in that it was a progressive freezing process, not a suspension crystallization process. In progressive freezing, pure hydrazine crystallizes on a surface cooled in a heat exchanger while the solution to be purified flows over the crystals and the cold surface and recirculated (vertical falling film) until the desired fraction of liquid has been immobilized and the impurities accumulate in the sump of the crystallizer. The purified hydrazine crystals build up on the cooled surface in layers like stalactites in a limestone cave. However, a single freeze-thaw (crystallization-sweating) sequence does not provide sufficient purification, and the process is conducted as a multi-stage separation, where the purified product of the first stage is separated from the mother liquor and subjected to a second stage and so on for a total of five to six stages, depending on the purity of the feedstock. A flow schematic of the apparatus is shown in Figure 5.

**Figure 5:** Hydrazine purification plant flow sheet. (Courtesy of Astrium-Space Infrastructure, Germany.)

Starting with monopropellant-grade hydrazine (which is no longer made), five stages were sufficient to achieve a high-purity-grade product that met the high-purity-grade requirements of MIL-P-26536D. For the sodium hydroxide upper phase, at least six

steps were required. The impure liquids gathered from each stage can be combined and reworked to obtain an intermediate-grade hydrazine that can be recycled in a separate purification campaign and improve overall product yield and reduce the costs associated with disposing of hazardous waste. The hydrazine purification plant at Trauen was designed to produce 10 to 30 kg of high-purity-grade hydrazine per day and the operation was highly automated and computer controlled with a minimum of hands-on transfer operations required.

On a smaller scale, very pure hydrazine can be prepared by directional crystallization in the laboratory. This can be done by slow passage of the crystallization zone through a stirred sample in a large test tube, which is slowly (20 mm/h) lowered into a cold bath at 223 K [94]. See also [95].

### 1.6.2 Purification by Adsorption

Passing MIL-SPEC-grade hydrazine through a column filled with activated alumina will decrease the water content from 0.92 to 0.07% H<sub>2</sub>O [96]. The alumina column will become exhausted after several times its bulk volume in hydrazine has passed through the trickle column. The wet alumina can be regenerated and recycled by heating it slowly in a stream of nitrogen to 810 K. Aniline, once a frequent contaminant of hydrazine, can be selectively adsorbed on alumina. Attempts to achieve the same purification of aniline-containing anhydrous hydrazine with activated charcoal resulted in the ignition of the wet activated charcoal as soon as air was accidentally admitted to the hydrazine-wet charcoal at the end of the test. Without any precautionary warning, activated carbon was listed along with alumina and other desiccants in a competing patent [97].

Organics in hydrazine hydrate from a ketazine or peroxide process can be removed by adsorption on microporous organic polymer beads [98]. Traces of water can be removed from hydrazine by treatment with calcium hydride then passing the vapor through a molecular sieve Linde 3A column [99].

## 2 Physical Properties of Hydrazine Hydrate and Hydrazine

The physical properties of hydrazine and hydrazine hydrate are summarized in Table 1. Several other authors have published summaries of the physical properties of hydrazines [17–21, 100–102], but of course none of these summaries comes anywhere near the second edition of the hydrazine book [22] in terms of completeness of data to date. The thermodynamic properties of hydrazine were summarized on several occasions in other publications [103–106] (Section 2.2).

**Table 1:** Physical properties of anhydrous hydrazine and hydrazine hydrate.

| Property                                  | Unit                                                 | N <sub>2</sub> H <sub>4</sub> | N <sub>2</sub> H <sub>5</sub> OH |
|-------------------------------------------|------------------------------------------------------|-------------------------------|----------------------------------|

## 2.1 Mechanical Physical Properties of Hydrazine Hydrate and Hydrazine

### 2.1.1 Freezing and Melting Points of Hydrazine, Hydrazine Mixtures, and Hydrazine Compounds

The relatively high freezing point of hydrazine is a disadvantage when hydrazine is sent out into the vastness of outer space to provide propulsion on satellites, space probes, and piloted spacecraft. Special design complications (temperature probes, heaters, thermostats, albedo control, radiation shields) must be installed to prevent hydrazine from freezing. Despite all precautions, there are several instances where hydrazine in a satellite has frozen accidentally and jeopardized the mission.

Melting points of pure compounds frequently serve as a quick means for checking the purity of a sample. In many cases the melting point of hydrazine reported in the literature is inaccurate because the sample contained impurities. For the determination of freezing points, hydrazine and many hydrazine mixtures have a tendency to supercool, so freezing-point determination is not very accurate.

The melting and freezing points of hydrazine depend strongly on the purity of the sample used in the determination. Water has a very pronounced effect on the melting point of hydrazine (Figure 8), and many reported melting points disagree among each other as a result of the different purity of the sample used. A melting point of 274.69 K for pure hydrazine was extrapolated from a sample with a melting point of 274.56 K that analyzed as 99.75%  $\text{N}_2\text{H}_4$  [107].

Extrapolation of the melting point of hydrazine/water mixtures to 100%  $\text{N}_2\text{H}_4$  gave a calculated melting point of 275.16 K (35.6 °F) [108]. Ultrapure hydrazine purified by repeated recrystallization had a melting point of 275.35 K (2.2 °C), slightly higher than commonly reported literature data [109]. Purified hydrazine with 0.01% water and less than 1 ppm of other impurities was found to have a freezing point of  $274.655 \pm 0.002$  K ( $1.495 \pm 0.002$  °C) [110].

#### 2.1.1.1 Triple Point of Hydrazine

A true measured triple point of hydrazine has not yet been reported. In analogy to that of water, it is assumed to be close to the freezing point of hydrazine at ambient pressure, which is 274.82 K (1.67 °C). Hydrazine leaking into vacuum will quickly freeze and assume triple-point conditions. The rate of hydrazine sublimation may be very low, depending on available sources of heat. Hydrazine spilled on a space suit during extra vehicular activities (EVA) may not evaporate quickly enough and could be dragged into the space station after the astronauts enter the air lock [111]. Like ice nuclei of comets, chunks of frozen hydrazine in outer space mixed with frozen ammonia are suspected of occurring on some outer planets and moons and may survive for very long periods of time.

### 2.1.1.2 Pressure Dependence of Freezing Point

The freezing point of hydrazine is dependent on pressure. Unlike water ice, the freezing point of hydrazine shifts to higher temperatures with increasing pressure. Researchers became painfully aware of this phenomenon when a hydrazine-powered buoyancy inflation system failed to operate at low temperatures at the bottom of the ocean, surrounded by very high pressure. The hydrazine in the pressure-equilibrated propellant supply tank had frozen.

For high-pressure applications of hydrazine, it may be occasionally overlooked that the freezing point of hydrazine is a function of pressure. During a deep-sea experiment for buoyancy generation with hydrazine, the propellant was found to freeze at depths below 2880 m (9500 ft) and an ocean water temperature of 274.7 K (1.55 °C = 34.8 °F), which came as a surprise to many observers. Subsequent investigation showed that theoretically the freezing point increases from 275 K at ambient pressure to 279 K at 60 MPa [112]. The pressure dependence of the freezing point can be expressed by the Clausius-Clapeyron equation

$$\frac{dp}{dt} = \frac{\Delta H_{\text{melting}}}{T(V_{\text{liquid}} - V_{\text{solid}})}$$

where  $\Delta H$  is the heat of fusion and  $V$  the specific volume of the liquid and solid, respectively. With numerical data inserted, this equation becomes

$$T_f = T_{fa} e^{\frac{p-1}{38000}}$$

where  $T_{fa}$  is the freezing point at ambient pressure and  $p$  is the pressure in bar (1 bar =  $10^5$  Pa). For example, the increase in the freezing point is 0.39 °C (0.70 °F) for an increase of 4.1 MPa (600 psig) in pressure [113]. If the pressurant gas is nitrogen and the frozen hydrazine is saturated with nitrogen, the freezing point will be lowered by the presence of dissolved nitrogen. The depression of the freezing point,  $\Delta T_{fr}$ , for dissolved nitrogen can be calculated from

$$\chi_2 = 0.02011 \Delta T_{fr}$$

where  $\chi_2$  is the mol fraction dinitrogen. The result from this equation is  $\Delta T_{fr} = -0.011$  °C.

Figure 6 shows the dependence of the freezing point of hydrazine on ambient pressures, up to very high pressures, which may be encountered by deep-sea underwater vehicles at the bottom of oceans. For those deep-sea applications, the dependence of the freezing point on pressure becomes a very important design consideration (see *Encyclopedia of Monopropellants*, chapter “Hydrazine Monopropellants”). It may have been for this reason that hydrazine monopropellant gas generant for a submarine emergency deballasting system was amended with some ammonia to lower its freezing point. The other research area where hydrazine is taken to very high pressures, usually in a diamond anvil cell, is in the search for other hydronitrogen compounds.

**Figure 6:** Freezing point of hydrazine as a function of pressure. (Reproduced and modified from [22].)

### 2.1.1.3 Supercooling of Freezing Hydrazine

When studying the supercooling of hydrazine, it has been found that hydrazine could be supercooled by 70 K in capillaries, whereas under the same conditions water could be supercooled by only 35.5 K and benzene by only 54.5 K [114]. Hydrazine used for these tests had to be specially purified and freed from condensation nuclei. When liquid hydrazine is flash-evaporated into vacuum, some of it evaporates and some of it freezes to hydrazine “snow” at the triple point. Liquid hydrazine has been observed to supercool when first exposed to vacuum.

The high degree of supercooling that can be observed with small droplets of hydrazine cannot be achieved with bulk quantities of hydrazine in the tank of a satellite. For all practical purposes, one must assume that pure hydrazine will freeze at 274.6 K, although in a few instances it will supercool and refuse to freeze. For some applications of hydrazine, the relatively high freezing point of hydrazine is a serious shortcoming. One cannot rely on supercooling of hydrazine or hydrazine blends as a method to extend the liquid range. It may or may not freeze soon after the temperature drops below the literature freezing point.

#### 2.1.1.4 Melting and Freezing Points of Hydrazine Hydrate

The melting point of hydrazine hydrate (64%  $\text{N}_2\text{H}_4$  in  $\text{H}_2\text{O}$ ) as read from the freezing-point diagram of the hydrazine/water system (Figure 8) is 221.48 K ( $-51.67^\circ\text{C} = -61^\circ\text{F}$ ) [108]. Like other hydrazine blends, hydrazine hydrate also has a tendency to supercool, and experimental freezing-point determinations are not very accurate. Accurate freezing points for supercooling liquids are usually extrapolated from phase diagrams.

#### 2.1.1.5 Problems with Freezing Hydrazine

Unlike water, hydrazine does not expand on approaching the freezing point and freezing. Unwanted freezing of hydrazine in spacecraft in the shadow of the Earth or at great distances from the Sun is a design problem that has occupied many thermal analysts and component engineers. In many cases, electrical heaters are wrapped around the tanks and propellant lines to keep them warm and prevent the hydrazine from freezing. This is one of the few complications caused by the high freezing point of hydrazine. It is obvious that the freezing of hydrazine will block flow. Partial freezing may cause liquid flow restrictions. In addition to flow restrictions that are reversible after the spacecraft returns to warmer regions or after the line heater power is increased, there is concern about lines rupturing as a result of freeze-thaw cycles, resulting in catastrophic failure of a satellite propulsion subsystem. In most instances freezing is undesirable, but in an isolated case, such as in some TIROS/DMSP spacecraft, it was desirable, and the propellant was allowed to freeze on purpose to prevent it from sloshing around. For this satellite, the hydrazine was used only for orbit insertion and initial orbit adjustment. After the satellite achieved the desired orbit, the propellant was allowed to freeze on purpose to minimize slosh disturbance of the gravity-stabilized satellite with a cold gas attitude control system (ACS). If such a spacecraft experiences freeze-thaw cycles, or the albedo of reflecting surfaces changes after years in space, propellant lines may rupture when warming from the wrong end [115]. Since hydrazine, unlike water, does not expand on freezing, the freezing alone does not cause a problem for the spacecraft. It is only where thawing may start from the same end from where freezing started a few orbital revolutions or a few days earlier that line rupture may result. Gaps formed between tubing wall and the slug of hydrazine during previous freezing events will fill in with liquid and freeze on the next partial freeze-thaw cycle. It is only in the case of repeated freeze-thaw cycles, only if thawing starts from the same end as the freezing, where very high pressures can occur because a slug of frozen hydrazine will still prevent the escape of the expanding melt. It is suspected that at least one spacecraft was lost due to the rupture of hydrazine lines during freeze-thaw cycles.

### 2.1.2 Freezing Points of Hydrazine Mixtures

Various additives have been tested as freezing-point depressants for hydrazine. The types of additives that meet certain criteria depend on the planned use of hydrazine, which could be either as a fuel in a bipropellant engine or as a monopropellant in a monopropellant engine. A low-freezing blend intended as a bipropellant fuel is allowed to contain organics like MMH, UDMH, or methanol. A low-freezing monopropellant may not contain any organics, or the carbon would poison the catalyst. Low-freezing monopropellant blends of hydrazine with MMH or other organics can be used in thermal bed (as opposed to catalytic) gas generators that are insensitive to carbon poisoning. Most freezing-point-depressing additives to hydrazine result in a decrease of rocket performance. An exception is hydrazinium nitrate (HN), which lowers the freezing point and increases the performance as a monopropellant at the same time.

One of the main disadvantages of hydrazine in view of its various uses for space propulsion and other applications is its high freezing point. Accordingly, numerous attempts have been made to lower its freezing point by freezing-point-depressing additives. The selection of additives is frequently limited by other considerations, such as loss of performance, increased corrosion, initial instability, or catalyst poisoning. The most thoroughly studied freezing-point-decreasing additives include water, MMH, UDMH, ammonia, and HN. For the use of hydrazine as a rocket propellant under low-temperature battlefield or outer space conditions, additives were sought that would at the same time increase its performance as a monopropellant or as a bipropellant fuel. Additives that meet these objectives are oxidizers for monopropellants or compounds with high heats of combustion as bipropellant additives.

Theoretical freezing-point depression can be calculated from the equation

$$\lambda = \frac{MRT_f^2}{1000\Delta H_f}$$

where  $M$  is the molecular weight of the solvent,  $R$  is the universal gas constant in calories per mol per degree,  $T_f$  is the freezing point in K, and  $\Delta H_f$  is the molar heat of fusion. The molal freezing-point depression constant  $\lambda$  of hydrazine was calculated from the preceding formula to be 1.5916 based on a heat of fusion of 12.63 kJ/mol at 274.7 K (3.020 kcal/mol at 1.6 °C) [116]. This equation is only valid for nondissociating freezing-point depressants. Salts will typically dissociate into ions and thus increase their effectiveness as freezing-point depressants. Depending on the number of ions formed and the degree of dissociation, degree of dimerization, and ratio of solvation, the effective freezing-point depression may differ substantially from that predicted by the foregoing equation. This relationship is illustrated in Figure 7, where curve 1 represents an ideal solution, curve 2 assumes solvation of one molecule of solvent with one molecule of solute, curve 3 assumes solvation of two molecules of solvent with one molecule of solute, curve 4 assumes complete dissociation into two different ions, and curve 5 assumes the solute remains associated to dimers in hydrazine (which reduces its effectiveness as a freezing-point depressant).

Figure 7: Theoretical freezing-point depression of hydrazine. (Reproduced and modified from [22].)

### 2.1.2.1 The Hydrazine/Water System

Propellant mixtures of hydrazine and water are important for several reasons. First, all hydrazine that is currently made starts out as a hydrazine/water solution. Second, hydrazine hydrate is used as a fuel ingredient in UH25, a hypergolic fuel blend with UDMH. Third, the H-70 used as a gas generant in the F-16 Emergency Power Unit (EPU) is a hydrazine/water blend with a low freezing point.

As simple as it may seem at first glance, the binary system hydrazine/water is in reality very complex. It has been investigated several times over the centuries since it was first discovered, and each time the investigators found something new. The investigation of the phase diagram of the hydrazine/water system often had a practical purpose: It was hoped that by simple freezing or even multiple freezing cycles it would be possible to enrich hydrazine in solution, thereby avoiding the sometimes hazardous distillations. Purification of hydrazine by freeze-thaw cycles was already discussed in Section 1.6. The formation of hydrazine hydrate as a well-defined compound is clearly expressed as a peritectic in the melting-point diagram of the hydrazine/water system. The melting-point diagram in Figure 8 shows two eutectic compositions, one at 69 mass-% (219 K) and one at approximately 41 mass-% with a freezing point below 190 K [108].

The conversion of mass percentage to mol percentage in aqueous solutions is achieved by

$$\text{mol-\% N}_2\text{H}_4 = \frac{100}{1 + \left( \frac{100 - \text{mass-\%}}{\text{mass-\%}} \right) \left( \frac{32.045}{18.015} \right)}$$

The conversion in the opposite direction is accomplished using

$$\text{mass-\% N}_2\text{H}_4 = \frac{100}{1 + \left( \frac{100 - \text{mol-\%}}{\text{mol-\%}} \right) \left( \frac{18.015}{32.045} \right)}$$

**Figure 8:** Freezing point of hydrazine/water mixtures. (Reprinted and modified from [108], with permission of ©American Chemical Society; permission conveyed through RightsLink.)

Hydrazine or water by themselves do not supercool to a large extent, but their mixtures do so noticeably. Many hydrazine/water mixtures do not show a distinct freezing point but rather solidify gradually to a highly viscous, glassy material. During the transition period as the temperature of the mixture approaches the freezing point (if it ever freezes), the material has a very high viscosity. Early freezing-point investigations published in 1949 did not cover the complete range of compositions because of difficulties encountered at lower temperatures. Subsequent reexamination in 1951 showed water-hydrazine mixtures freezing at record low temperatures, down to 183 K for a eutectic 40.5% hydrazine/59.5% water mixture [117]. The higher freezing eutectic was recorded at 69.3 mass-%  $N_2H_4$ , melting at 219.6 K. Later investigations assigned a univariant equilibrium at 28 mol-% to the same eutectic as that observed by Hill and Sumner [118]. The melting point and composition of the water-rich eutectic of hydrazine and water were determined by differential thermal analysis as  $193 \pm 0.5$  K and  $27 \pm 1$  mol-% hydrazine, respectively [119]. Some of the mixtures turned into a rigid glassy state without ever crystallizing. Some crystallized belatedly on warming from the glassy state. Some crystallized only after being cycled around the freezing/melting point several times at very slow heating/cooling rates of  $1^\circ/\text{min.}$  or less. Some release the heat of crystallization suddenly, causing a distinct exotherm.

Glass transformation temperatures can be measured repeatedly at the same point. A time/activation energy relationship can be established if plotting the warmup-crystallization temperature as a function of the warmup rate and the sample's thermal history [120]. Since some of these non-equilibrium phase transitions are not visible to the naked eye of an observer, they can only be identified by heat capacity measurements or differential thermal analysis or differential scanning calorimetry. There are indications of the existence of a tetrahydrate  $\text{N}_2\text{H}_4 \cdot 4\text{H}_2\text{O}$  at 20 mol-% that forms a eutectic (containing 28 mol-%  $\text{N}_2\text{H}_4$ ) with the monohydrate. However, the behavior in this region of the phase diagram is not very reproducible, discouraging investigators from additional experimentation. The tetrahydrate melts incongruently at 193 K. Consequently, there are four univariant equilibria in the  $\text{N}_2\text{H}_4/\text{H}_2\text{O}$  solid system shown in the phase diagram in Figure 9.

**Figure 9:** Phase diagram of hydrazine/water system. (Republished and modified from [119], with permission of ©1965 AIP Publishing; permission conveyed through RightsLink)  
 Legend:  $\Lambda$  = Liquid phase;  $\alpha$  =  $\text{H}_2\text{O}(\text{S})$  = water ice;  $\beta$  =  $\text{N}_2\text{H}_4 \cdot 4\text{H}_2\text{O}(\text{S})$ ;  $\gamma$  =  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}(\text{S})$ ;  $\delta$  =  $\text{N}_2\text{H}_4(\text{S})$ .

The thermodynamics and kinetics of crystallization during warmup of hydrazine hydrate from a supercooled solution are very complex. There are several unknowns in trying to express this process mathematically. It appears that liquid layers close to the growing crystal are already in a partially ordered state [121].

The peritectic at 50 mol-%  $\text{N}_2\text{H}_4$  + 50 mol-%  $\text{H}_2\text{O}$  is due to a distinct compound, hydrazine hydrate,  $\text{N}_2\text{H}_5\text{OH}$ , not just a simple hydrate  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}$ . The existence of this discrete compound is also supported by vapor density and viscosity measurements. This compound has thus been assigned its own CAS registry number, different from that of hydrazine. Hydrazine solutions in more than 36% water should be called hydrazine hydrate solutions. Chemical manufacturers often use the wrong CAS number on the labels of hydrazine hydrate and hydrazine hydrate solution drums and Material Safety Data Sheets (MSDSs). They often use the CAS number for anhydrous hydrazine when they should be using the CAS number for hydrazine hydrate.

DSC measurements of hydrazine/water mixtures with a hydrazine mol fraction of 0.4 showed three distinct endotherms between 220 and 130 K [122, 123]. Phase transformations in the solid state document themselves by changes in the Raman spectra of the solids, in particular in the regime of  $2900\text{ cm}^{-1}$ , where OH and NH vibrations are seen, and also at  $3340\text{ cm}^{-1}$ .

### 2.1.2.2 The Hydrazine/Ammonia System

Hydrazine and ammonia are both hydronitrogens. Both are being or have been used as rocket fuels. As close relatives of the same family of chemical compounds, they are totally miscible with each other over the entire range of compositions. Ammonia is one of the products of slow decomposition of hydrazine during storage, so aged hydrazine always has a little ammonia dissolved in it. Ammonia can be added to hydrazine to lower its freezing point and flame temperature. However, adding ammonia to hydrazine will lengthen the ignition delay and shorten the catalyst life when many start-ups are needed. Hydrazine can be added to ammonia to improve its hypergolic ignition with nitric acid or dinitrogen tetroxide (NTO) as the oxidizer.

### 2.1.2.3 Hydrazine/Alcohol Systems

Both hydrazine and ethanol are used as rocket fuels. Mixtures of hydrazine and alcohols were once studied as bipropellant fuels. These mixtures can combine the hypergolicity of hydrazine with the low freezing points of alcohols. The melting-point diagram of hydrazine and methanol mixtures showed three addition compounds,  $\text{N}_2\text{H}_4 \cdot \text{CH}_3\text{OH}$ ,  $\text{N}_2\text{H}_4 \cdot 2\text{CH}_3\text{OH}$ , and  $\text{N}_2\text{H}_4 \cdot 4\text{CH}_3\text{OH}$ , which melted at 225.7, 215.3, and 203.6 K ( $-47.3$ ,  $-57.8$ , and  $-69.5^\circ\text{C}$ ), respectively [124, 125]. Eutectics were found that melt at 213 and 173 K but did not exhibit distinct freezing-point minima. In contrast, the hydrazine/ethanol system showed the existence of only one addition compound,  $\text{N}_2\text{H}_4 \cdot 2\text{C}_2\text{H}_5\text{OH}$ , which melted at 241.9 K ( $-31.2^\circ\text{C}$ ). The eutectic between hydrazine and the addition compound contained 45 mol-% hydrazine and melted at 239.4 K ( $-33.7^\circ\text{C}$ ).

In a continuation of these studies with methanol and ethanol, higher  $C_{\geq 2}$  alcohols were investigated as freezing-point depressants and fuel additives [126, 127]. The hydrazine/*n*-propanol system resembled the hydrazine/ethanol system in exhibiting one weak addition compound,  $N_2H_4 \cdot 2C_3H_7OH$ , melting point 231.8 K ( $-41.3^\circ C$ ). A eutectic at 65 mol-% propanol melted at 230.7 K ( $-42.4^\circ C$ ). The hydrazine/isopropanol system was more complex and showed several deflections before reaching a eutectic at 96 mol-% *iso*- $C_3H_7OH$ , melting point 183 K ( $-90^\circ C$ ). The two inflections were attributed to the polymorphism of hydrazine. Mixtures with allyl alcohol showed the formation of a 1:2 compound that melted at 205 K ( $-68^\circ C$ ). A eutectic of this compound and hydrazine contained 62 mol-% allyl alcohol and solidified at 204 K ( $-69^\circ C$ ). Thus, none of the higher alcohols is as effective as freezing-point depressant as methanol or water. The hydrazine/propargyl alcohol system has also been investigated [128]. Propargyl alcohol would be a good fuel because it has a high heat of combustion since it contains a  $C \equiv C$  triple bond. Of all the alcohols tested as freezing-point depressants, propargyl alcohol was the most active freezing-point depressant.

Glycerol and other hydroxyl compounds have been evaluated as freezing-point depressants for hydrazine [129]. Addition of 20% glycerol lowered the freezing point of hydrazine to 258.1 K.

#### 2.1.2.4 The Hydrazine/MMH System

The most frequently used hydrazine/MMH mixture is the 14 mass-% hydrazine/86% MMH mixture ("M-86," "MHF-3") with a freezing point of 219 K ( $-65^\circ F$ ). Another hydrazine/MMH mixture of practical interest is Ae-76, a blend of 76% MMH and 24% hydrazine formulated by Aerojet to contain the same amount of carbon as Aerozine-50 and at one time intended as a replacement for Ae-50. It freezes at  $\sim 237$  K ( $-33^\circ F$ ). A third blend of interest is M-20, containing 20% MMH in hydrazine, freezing at  $\sim 269$  K ( $25^\circ F$ ), and proposed as a replacement for hydrazine in bipropellant rocket engines. Hydrazine/MMH fuel blends will be described in this set's chapter "Methylhydrazine."

#### 2.1.2.5 The Hydrazine/UDMH System

Both hydrazine and UDMH are excellent rocket fuels, as evidenced by their widespread use as hypergolic fuels with NTO. The mixture of hydrazine and UDMH, also called Aerozine-50, Ae-50, A 50, a 50:50 (by weight) mixture of hydrazine and UDMH, was formulated to be suitable as a regenerative coolant in bipropellant rocket engines. The lower melting point was only a secondary benefit of adding UDMH to hydrazine without losing performance as a rocket fuel. Aerozine-50 freezes/melts at 265–267 K ( $17.6$ – $21.2^\circ F$ ). There is a eutectic point at 214 K ( $-74.5^\circ F$ ) close to the UDMH end of the system at 96.7 mass-% UDMH [130]. The freezing point of the system  $N_2H_4$ /UDMH is illustrated in the chapter on dimethylhydrazines (Figure 31). Ae-50 that leaks past a valve and is suddenly exposed to vacuum will cool (mainly by evaporation of UDMH), and the remaining hydrazine-rich fuel will freeze at the triple point, clogging the injector tubes [131]. Evaporation of Ae-50 in

propellant valve seats or narrow passages under space vacuum conditions may clog the tubes and prevent fuel flow [132, 133]. The freezing points of hydrazine/UDMH mixtures under those shifting conditions with diminishing UDMH content must be known to better understand this potential failure mode. Hydrazine/UDMH fuel blends will be described in more detail in the present publication in the chapter on dimethylhydrazines.

#### 2.1.2.6 The Hydrazine/EDH System

One way to reduce the undesirably high vapor pressure and associated toxicity hazard of hydrazine/UDMH mixtures is to substitute a low-volatility hydrazine for UDMH. One such low-volatility hydrazine is ethylenedihydrazine (EDH) (1,2-dihydrazinoethane or 1,2,5,6-tetraazahehexane). The physical properties of hydrazine/EDH mixtures are presented in *Encyclopedia of Liquid Fuels*, chapter “Alkylhydrazines.” The freezing point of the binary system shows a minimum near 80% EDH. One disadvantage of EDH is that it is very viscous. Hydrazine addition would lower the viscosity.

#### 2.1.2.7 Hydrazine/Amine Systems

Freezing-point depressants that are chemically similar to hydrazine or alkylhydrazines, such as alkyl or aryl amines, are expected to have the necessary solubility in hydrazine and contribute to the fuel value to result in practical propellant blends. Methylamines (mono- and dimethylamine) have been considered as freezing-point-depressing additives to hydrazine. Surprisingly, trimethylamine is not miscible with hydrazine. Freezing-point curves of ethylamine mixtures with hydrazine (95.5% hydrazine, some water contamination) are shown in Figure 10.

Ethylamine is not effective as a freezing-point depressant, the eutectic mixture freezing at only 271 K ( $-2^{\circ}\text{C}$ ) in dry hydrazine. Ethylenediamine is slightly more effective (261 K =  $-12^{\circ}\text{C}$ ) but still a long shot from reaching a typical goal of a 219 K =  $-65^{\circ}\text{F}$  =  $-54^{\circ}\text{C}$  freezing point. Diethylenetriamine and hydrazine form a eutectic at 97% diethylenetriamine, which freezes near 232 K ( $-41^{\circ}\text{C}$ ) and has a tendency to supercool [135]. A comparison of ethylamine, ethyleneimine, and aniline is given in Figure 10. Note that in this example, which used hydrazine with several percent water, ethylamine achieved low-freezing mixtures down to only 267 K ( $-6^{\circ}\text{C}$ ). Ethyleneimine is not an acceptable additive because of its high toxicity. The gross composition of many alkylamine/hydrazine blends as fuels in bipropellant rockets would be similar to Aerozine-50, but the vapor pressure would be much higher. Hydroxylamine, cyanamide, and methoxyamine (*O*-methylhydroxylamine) react with hydrazine and were found to be unfit as freezing-point depressants [136]. Twenty percent diethylenetriamine in hydrazine will lower the freezing point to 262 K [129].

Aniline mixtures have been used as rocket fuels. Aniline flew in sounding rockets before anhydrous hydrazine did. The eutectic mixture of hydrazine and aniline contains 18% hydrazine and melts at 234 K ( $-39^{\circ}\text{C}$ ) [137, 138] (Figure 10). Addition of only 20% hydrazine to aniline lowered the ignition delay with NTO by several orders

**Figure 10:** Comparison of three amines and ethylenedihydrazine as freezing-point depressants in hydrazine. (Image created by Schmidt 2020, based on data from [134].)

Note: The hydrazine contained several percent water.

of magnitude. Diphenylamine is used as a stabilizer in double-base propellants. In one study, 26 mol-% diphenylamine lowered the freezing point of hydrazine to 236 K ( $-37^{\circ}\text{C}$ ). Data were also available for the range from 48 to 100 mol-% diphenylamine where the melting point continually increased from 314 K ( $41^{\circ}\text{C}$ ) to 327 K ( $54^{\circ}\text{C}$ ).

#### 2.1.2.8 Hydrazine/Amide Systems

It is uncertain to what extent mixtures of hydrazine and amides can be investigated without substitution of the  $-\text{CO}-\text{NH}_2$  amido group and formation of hydrazides  $-\text{CO}-\text{NH}-\text{NH}_2$ . Acetamide in hydrazine shows one freezing-point minimum at 22.5 mol-% acetamide, melting point 259.5 K ( $-13.6^{\circ}\text{C}$ ). Similarly, the hydrazine-urea system exhibits a minimum freezing point of 243.7 K ( $-29.4^{\circ}\text{C}$ ) near 31.4 mol-% urea. It is likely that compound (hydrazide) formation has been overlooked during all these freezing-point determinations. Some freezing-point determinations were made immediately after dissolving the amide and again several days later, showing significant differences in freezing points. Guanidinium nitrate in anhydrous hydrazine would convert to triaminoguanidinium nitrate. Triaminoguanidine and its salts are considered to be freezing-point depressants, but they are not very soluble. Triaminoguanidinium nitrate was not found to be suitable for this application as a freezing-point depressant [139].

#### 2.1.3 Freezing Points of Solutions of Solids in Hydrazine

Because hydrazine freezes at a comparatively high temperature, its useful range can be extended by suitable freezing-point-depressing additives. The additives can be neu-

tral molecules, as shown in the previous section, or they can be saline compounds. Selection criteria limit the number of practical freezing-point-depressing additives to only a few candidates, which must have compatibility with hydrazine, stability in hydrazine solution, sufficient solubility in hydrazine, a positive effect on rocket propellant performance of hydrazine, and minimal corrosion.

Many of the ionized compounds, such as hydrazinium(1+) nitrate, when dissolving in hydrazine will cause a freezing-point depression beyond that expected from their molecular weight. This is caused by the dissociation of neutral molecules into ions under the effect of hydrazine as a solvent. Solutions of freezing-point-depressing salts in hydrazine can be based on hydrazine by itself as the solvent (resulting in binary systems) or on hydrazine mixtures as solvents, resulting in ternary systems. The relative efficiency of additives in lowering the freezing point of hydrazine is illustrated in Figure 11. Water and ammonia lower the freezing point more efficiently than do hydrazinium salts ( $\text{HN}$  or hydrazinium azide,  $\text{N}_5\text{H}_5$ ,  $\text{HA}$ ), but these additives decrease the performance of these mixtures as monopropellants.

**Figure 11:** Comparison of freezing-point-depressing additives to hydrazine. (Reproduced and modified from RRC Hydrazine Handbook.)

### 2.1.3.1 Binary Systems Hydrazine/Hydrazinium Salts

Binary systems of hydrazine with hydrazinium salts have been most extensively investigated (Table 2).

**Table 2:** Minimum freezing points of solutions of hydrazinium salts in hydrazine.

| Compound                    | Composition, salt mass-% | Freezing point |       | References |
|-----------------------------|--------------------------|----------------|-------|------------|
|                             |                          | K              | °F    |            |
| Hydrazinium azide           | 23.7                     | 257            | 3     | [140]      |
| Hydrazinium azide           | 20 E                     | 255.3          | 0     | [129]      |
| Hydrazinium azide           | 23.8                     | 258            | 5     | [141, 142] |
| Hydrazinium sulfide         | 18% H <sub>2</sub> S     | 243            | −23   | [143]      |
| Hydrazinium(1+) nitrate     | 45 E                     | 223.3          | −57.6 | [144]      |
| Hydrazinium(1+) perchlorate | 50 E                     | 205            | −90.4 |            |

E = eutectic composition

In a few cases, the mixtures can be prepared by **very slow** direct addition of the salt-forming acid to pure, anhydrous hydrazine. In most cases, this is not possible because of the strong exothermicity of the salt-forming reaction that may cause explosive decomposition of hydrazine. It is safer and more accurate to prepare the solution by another method: Weigh the previously prepared and dried salt first, and then dissolve it in hydrazine. Another method that makes use of metathetical reactions is to dissolve the corresponding ammonium salt in an excess of hydrazine and then remove the ammonia by sparging with an inert gas.

Hydrazinium nitrate is here often abbreviated as HN. This abbreviation is not to be confused with the diatomic imidogen radical NH. The binary system hydrazine/hydrazinium nitrate has been thoroughly investigated ([144], see Figure 1 in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers” and [145] and [146]). The phase diagram indicated the formation of a hydrazinium nitrate hydrazinate  $\text{N}_2\text{H}_5\text{NO}_3 \cdot \text{N}_2\text{H}_4$  with a melting point of 274.8 K (+1.7 °C). There are two eutectics, one each located on either side of the 1:1 compound, the lower-melting eutectic containing 45% HN and melting at 223.3 K (−49.8 °C = −57.6 °F). Hydrazine/hydrazinium nitrate solutions have been tested as monopropellants (see *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants”) [147, 148].

The binary system hydrazine/hydrazinium azide has been investigated repeatedly, with a eutectic mixture reportedly melting at 255.6 K (−17.5 °C) and containing 77%  $\text{N}_2\text{H}_4$  [149] (Figure 44 in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers”). Other investigators found a minimum melting composition at 258 K (−15 °C) that contained 76.2%  $\text{N}_2\text{H}_4$  [142, 150]. Finally, a third party arrived at a melting point of 257 K with a mixture containing 76.3% hydrazine [140]. These variations in melting

point were most likely caused by unrecognized traces of water in the mixtures. The ternary system  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{N}_3/\text{H}_2\text{O}$  has been investigated for four hydrazine-water solvents initially containing 85.2, 90.5, 95.9, and 98.8%  $\text{N}_2\text{H}_4$  (Figure 45 in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers”). Hydrazine/hydrazinium azide solutions have been tested as monopropellants [151].

Hydrocyanic acid has been considered as a freezing-point depressant for hydrazine propellant [152, 153], but safety concerns have prevented the use of this fuel because the dissociation constant of hydrazinium cyanide is high, and free HCN exists in the vapor phase above the liquid. Later investigations noted that hydrazinium cyanide solutions decomposed with gas evolution at 344 K. Another of the pseudohalogenide salt additives studied as a freezing-point depressant for hydrazine is ammonium thiocyanate [154]. Hydrazine-ammonium thiocyanate mixtures can be analyzed by redox titration with potassium iodate and ammonia removal by Kjeldahl distillation, followed by acidimetric titration [155, 156]. The ability of ammonium thiocyanate to form low-freezing, low-vapor-pressure solutions in hydrazine is like the formation of Divers’ solution of ammonium thiocyanate in ammonia, which is a low-vapor-pressure (compared to liquid ammonia) liquid that can be stored at room temperature.

Eutectic mixtures of hydrazine and hydrazinium sulfide containing 82 mass-% hydrazine and 18% hydrogen sulfide freeze at 243 K ( $-30^\circ\text{C} = -23^\circ\text{F}$ ) and were proposed as fuels for bipropellant engines [143]. The freezing point can be lowered further by making ternary mixtures with a little water, which lowers the freezing point to 233 K ( $-40^\circ\text{C} = -40^\circ\text{F}$ ). This fuel is not environmentally friendly.

### 2.1.3.2 Binary Systems of Hydrazine with Other Salts

If one is looking for salts to lower the freezing point of hydrazine, the first choice would be hydrazinium salts. Other salts have been tested for this purpose. In the case of ammonium salts, the freezing point would depend on retaining the volatile free ammonia that is formed as a result of the metathetical reaction between the ammonium salt and hydrazine. Table 3 lists the freezing points of salt solutions other than hydrazinium salts, although only a few of these may be useful as propellants.

### 2.1.3.3 Binary Systems of Solutions of Other Nonionized Compounds in Hydrazine

Besides salts that typically dissociate in hydrazine as a polar solvent (thereby increasing their effectiveness as freezing-point depressants), numerous other nonionizing compounds (mostly organics) have been tested as freezing-point depressants for hydrazine. First among these are hydrazine derivatives such as carbonohydrazide, because it was thought that, owing to their structural similarity, they should have good solubilities in hydrazine. Other compounds proposed included 5-aminotetrazole and nitroguanidine [161]. Freezing-point data for non-ionized compounds dissolved in hydrazine are summarized in Table 4.

**Table 3:** Hydrazine solutions of freezing-point-depressant salts.

| Salt compound                                | Additive concentration | Freezing point |            | References |
|----------------------------------------------|------------------------|----------------|------------|------------|
|                                              | Mass-%                 | °C             | K          |            |
| Ammonium perchlorate                         | 5.68                   | −3             | 270.1      | [157]      |
| Ammonium perchlorate                         | 9.99                   | −6             | 267.1      |            |
| Ammonium perchlorate                         | 14.71                  | −10.2          | 262.9      |            |
| Ammonium perchlorate                         | 20.20                  | −14.4          | 258.7      |            |
| Ammonium perchlorate                         | 25.15                  | −21.3          | 251.8      |            |
| Ammonium perchlorate                         | 31.15                  | −25.61         | 247.54     |            |
| Ammonium tetrafluoroborate                   | 20                     | −12.2          | 260.9      | [129]      |
| Ammonium thiocyanate                         | 32                     | −53.9          | 219.2      |            |
| Hydroxylammonium chloride                    | 20 (E)                 | −11            | 262        | [158]      |
| Lithium borohydride                          | 15                     | −46            | 227        |            |
| Sodium borohydride                           | 15                     | −25            | 248        |            |
| <i>N</i> -Methylhydroxylammonium chloride    | 30 (E)                 | −47.6          | 225.3      |            |
| <i>O</i> -Methylhydroxylammonium chloride    | 30 to 35               | −40 to −60     | 233 to 213 |            |
| <i>O</i> -Methylhydroxylammonium perchlorate | 42                     | −54            | 219        | [159, 160] |
| Guanidinium nitrate                          | 27.5                   | −32            | 241        | [139]      |

**Table 4:** Freezing point of solutions of nondissociating liquids and solids in hydrazine.

| Compound                      | Additive concentration | Freezing point |       | References |

### 2.1.4 Freezing and Melting Points of Ternary Hydrazine Solutions

As opposed to a previous section that discussed all-liquid binary mixtures, this section summarizes information about ternary mixtures involving free hydrazine, one other liquid component, and one solid, dissolved salt. One of the most thoroughly investigated ternary systems involving free hydrazine (or hydrazine hydrate), one other liquid component, and one salt is the hydrazine/water/hydrazinium nitrate system. Hydrazinium nitrate is here often abbreviated as HN. This abbreviation is not to be confused with the diatomic imidogen radical NH. The  $\text{N}_2\text{H}_4/\text{H}_2\text{O}/\text{N}_2\text{H}_5\text{NO}_3$  system is separated into two regions by the boundary of detonability as described in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers.” Accordingly, it offers a wide range of propellants and explosives, depending on the choice of composition and the intended application. Next to performance as a propellant or explosive, melting point is the most important selection criterion. A detailed knowledge of the melting points, eutectic points, and eutectic valleys in the ternary system  $\text{N}_2\text{H}_4/\text{H}_2\text{O}/\text{N}_2\text{H}_5\text{NO}_3$  enables one to select propellants for maximum  $I_{\text{sp}}$  or lowest exhaust gas temperature within certain freezing-point boundaries. Military and deep-space applications frequently require freezing points below that of pure hydrazine. The physical, chemical, and safety properties of ternary  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$  mixtures were described in detail in *Encyclopedia of Oxidizers* in the chapter on hydrazinium salts.

Other ternary hydrazine mixtures consist of hydrazine, MMH, and HN. Freezing points of mixtures of hydrazine/MMH/HN and hydrazine/UDMH/HN have been thoroughly investigated (*Encyclopedia of Liquid Fuels*, chapter “Methylhydrazine”). A mixture with a nominal composition of 23.3% hydrazine, 45.3% MMH, and 31.4% HN freezes at 219 K (−65 °F) and has been named Mixed Hydrazine Fuel-1 (MHF-1).

The physical, chemical, and safety properties of ternary  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{N}_3/\text{H}_2\text{O}$  mixtures were described in detail in *Encyclopedia of Oxidizers* in chapter “Hydrazinium Salt Oxidizers.” The melting points and other physical properties of ternary hydrazine/ammonia/water mixtures were already described in *Encyclopedia of Liquid Fuels*, chapter “Ammonia.”

#### 2.1.4.1 Melting-Point Diagrams of Systems Including Hydrazinium Salts

Hydrazinium salts in mixture with other salts (mostly alkali metal salts) give low-melting eutectics with interesting properties.

#### 2.1.4.2 Phase Diagrams of Mixtures of Hydrazinium Salts with Other Salts

The first product of the Sisler process in anhydrous ammonia is a mixture of ammonium chloride and hydrazinium(1+) chloride. The binary system hydrazinium(1+) chloride/ammonium chloride in the range 0–23 mol-% ammonium chloride has been investigated as part of a study on the conversion of chloramine-ammonia reaction products from the Sisler process to free hydrazine by reaction with caustic or sodium amide in ammonia [162].

The hydrazinium salt with the highest level of interest as a rocket propellant is hydrazinium nitrate. It is too sensitive to be used in the dry state, but it has been used in a variety of solutions in hydrazine or MMH. The properties of hydrazinium nitrate (HN) are described in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers.” We must therefore look at the melting of hydrazinium nitrate and its mixtures with other nitrate salts. The eutectic compositions and melting points of mixtures of five alkali metal nitrates or ammonium nitrate with hydrazinium nitrate are listed in *Encyclopedia of Oxidizers* in the chapter “Hydrazinium Salt Oxidizers,” Table 3, based on data from [163]. No well-defined compounds or double salts could be identified in these binary systems.

It was possible to draw phase diagrams and triangular charts of ternary systems involving ammonium nitrate, hydrazinium(1+) nitrate, and any one of the following five nitrates using theoretical equations: lithium nitrate, sodium nitrate, potassium nitrate, hydroxylammonium nitrate, and hydrazinium(2+) dinitrate [164]. The data are summarized in *Encyclopedia of Oxidizers* in the chapter “Hydrazinium Salt Oxidizers,” Table 4. The lowest-melting eutectic in the latter system melted at only 300 K (27 °C). Even lower-melting systems are formed with small amounts of water contamination. Many of these low-melting eutectics are of practical interest in emulsion explosives or emulsion propellants. This is an interesting mathematical analytical technique for obtaining phase diagrams when experimental measurements are not yet available.

#### 2.1.4.3 Solutions of Hydrazinium Salts in Other Solvents

The most common other solvent for hydrazinium salts besides hydrazine is water. Solubility data for such systems frequently provide melting points along with solubility at the saturation point. The solubility of hydrazinium(1+) nitrate in water is summarized in *Encyclopedia of Oxidizers* in the chapter “Hydrazinium Salt Oxidizers,” Table 5. The solubility of hydrazinium(1+) perchlorate in water is summarized in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers,” Table 23. The solubility of hydrazinium nitroformate,  $\text{N}_2\text{H}_5\text{C}(\text{NO}_2)_3$ , HNF, in water at 293 K (20 °C) is 52.88 mass-% HNF [165]. The solubility of HNF in water is approximately 50 mass-% at 293 K (20 °C) and 80% at 328 K (55 °C). The melting point of the hydrazinium nitrate/water system has been investigated repeatedly over the years. The graph in *Encyclopedia of Oxidizers*, in the chapter on hydrazinium salts, Figure 2, is a combination of earlier and later data. The system has a simple eutectic containing 37.5 mass-% HN and melting at 263.9 K (−9.2 °C).

#### 2.1.5 Boiling Point of Hydrazine

If hydrazine did not have strong hydrogen bonding between molecules, its boiling point would be closer to that of ethane. A collection of boiling points from eleven different sources in the literature showed surprisingly close agreement among the data, and the spread was less than 1 °C [105]. Most boiling-point data were in the vicinity of

113.5°C (386.6 K). The average of eleven data points was 113.4°C (386.7 K). The boiling point of hydrazine is closely tied to the vapor pressure, which will be discussed in Section 2.1.9 below. In describing the physical properties of hydrazine and hydrazinium salts, precautionary remarks are highly appropriate regarding the explosive hazards of melting hydrazinium(1+) nitrate in bulk quantities or the boiling and possibly distilling of hydrazine and hydrazine derivatives at ambient pressure. Many hydrazine derivatives are simply too unstable to be boiled. Consequently, few boiling points of hydrazine derivatives are reported in the literature. Those that were found were mostly at reduced pressure. Additional boiling-point data can be derived from the vapor pressure curves of Section 2.1.9 below.

## 2.1.6 Density of Hydrazine

### 2.1.6.1 Density of Liquid Hydrazine

The density of hydrazine is sometimes difficult to determine, especially at higher temperatures when tiny bubbles of gases caused by incipient decomposition attach themselves to a float of a hydrometer or to the inside of a pycnometer, thus feigning high or low density. Therefore, care must be taken to carefully degas a sample prior to measurements and complete the test before any significant amount of gas has formed again.

Many sources exist for the density of pure hydrazine (Table 5). The most comprehensive set of data available was obtained with a double-distilled sample [166]. The temperature dependence of the density of hydrazine is best described by

$$\rho = 1.23078 - 6.2668 \times 10^{-4} T - 4.5284 \times 10^{-7} T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. This equation is a composite of the density data obtained by five different authors. The line in Figure 12 was drawn using this equation.

A slightly different equation was obtained using a combination of their own data and those of four previous authors [166]:

$$\rho = 1.2471 - 7.226 \times 10^{-4} T - 3.191 \times 10^{-7} T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. This equation represents all experimental data with a standard deviation of  $\pm 6 \times 10^{-4} \text{ g/cm}^3$ . Other authors obtained the following relationship, giving slightly higher densities [170]:

$$\rho = 1.1310 + 3.0983 \times 10^{-5} T - 1.410 \times 10^{-6} T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin.

The liquid density data listed in [7] can also be represented by the following equation [172]:

$$\rho = \rho_c + a(1 - \tau) + b(1 - \tau)^{1/2} + c(1 - \tau)^{1/3} + d(1 - \tau)^2$$

**Table 5:** Density of anhydrous hydrazine.

| Temperature |        | Density           | References |
|-------------|--------|-------------------|------------|
| K           | °C     | g/cm <sup>3</sup> |            |

| 278         | 5      | 1.0305            | [170]      |
| 293         | 20     | 1.0140            |            |

where  $\rho_c$  = critical density,  $\tau$  is the reduced temperature  $T/T_c$ ,  $T_c$  is the critical temperature ( $653\text{ K} = 380^\circ\text{C} = 716^\circ\text{F}$ ), and the following constants listed in Table 6 apply for English and SI units, respectively.

This equation fits the data up to  $640\text{ K}$  ( $367^\circ\text{C} = 692.6^\circ\text{F}$ ) within their probable experimental precision. Haws and Harden [172] incorrectly assumed that the data attributed to Audrieth and Ackerson-Ogg [7] were **saturated** liquid density data when actually they were not. The claim of saturation conditions of the experimental data they referenced and reported turned out to be unfounded. It can, thus, be maintained that no direct experimental determination of the **saturated** liquid density (liquid under its own vapor pressure) has ever been attempted. There is concern for the accuracy of liquid phase density data because the weak dependence of specific volume on

**Figure 12:** Density of liquid hydrazine. (Reproduced and modified from [171].)

**Table 6:** Coefficients for high-temperature density of hydrazine.

| Coefficients | English units<br>lb/ft <sup>3</sup> | SI Units<br>g/cm <sup>3</sup> |
|--------------|-------------------------------------|-------------------------------|
| $\rho_c$     | 14.4                                | 0.2307                        |
| a            | 86.820                              | 1.3907                        |

| c            | 17.716                              | 0.2838                        |
| d            | -60.654                             | -0.9715                       |

Data source: [172]

pressure. The source of other data used by Haws and Harden 1965 remains unclear, therefore suspicious. Other investigators [173] repeated this misinterpretation.

### 2.1.6.2 Density of Hydrazine Vapor

Vapor density measurements were made to determine the degree of association of hydrazine molecules to clusters in the vapor space. The pressure-volume-temperature (PVT) measurements carried out by Giguere and Rundle constitute basically the only

available data in the literature for the density of  $\text{N}_2\text{H}_4$  in the vapor phase. Their experimental data, tabulated in Table 7, are based on two samples of  $\text{N}_2\text{H}_4$  with different mass. Thus, the experimental points from 90 to 120 °C (363 to 393 K) belong all to the isochor  $\rho = 0.3653 \text{ kg/m}^3$  while the single test at 131 °C (404 K) corresponds to  $\rho = 0.95 \text{ kg/m}^3$ .

**Table 7:** Experimental  $P$ - $V$ - $T$  data for hydrazine vapor.

| Original units |              |                        |          | SI units |                          |                                   |                       |

| $t$<br>°C      | $P$<br>mm Hg | $V$<br>cm <sup>3</sup> | $m$<br>g | $T$<br>K | $p \times 10^{-4}$<br>Pa | $V \times 10^6$<br>m <sup>3</sup> | $m$<br>kg             |
| 90             | 265          | 213                    | 0.0778   | 363.15   | 3.533                    | 213                               | $7.78 \times 10^{-5}$ |
| 95             | 273          | 213                    | 0.0778   | 368.15   | 3.640                    | 213                               | $7.78 \times 10^{-5}$ |
| 100            | 277          | 213                    | 0.0778   | 373.15   | 3.693                    | 213                               | $7.78 \times 10^{-5}$ |
| 110            | 287          | 213                    | 0.0778   | 383.15   | 3.826                    | 213                               | $7.78 \times 10^{-5}$ |
| 120            | 294          | 213                    | 0.0778   | 393.15   | 3.920                    | 213                               | $7.78 \times 10^{-5}$ |
| 131            | 747          | 220                    | 0.2090   | 404.15   | 9.959                    | 220                               | $2.09 \times 10^{-4}$ |

Data source: [174]

The PVT experimental data of Giguere and Rundle relative to nonsaturated vapor are also superimposed (as circular symbols  $\otimes$  at  $\rho/\rho_c = 1.583 \times 10^{-3}$  and  $\rho/\rho_c = 4.120 \times 10^{-3}$ ) on the vapor pressure data shown in Figure 20.

When examining literature data for vapor density of hydrazine, it was noted that Kit and Evered 1960 [175] on page 102 of that book have incorrectly labelled as **saturated** the vapor whose density was calculated by them from the experimentally determined PVT data of Giguere and Rundle. Kit and Evered [175] and also Das and Kuloor [173] erroneously assumed the PVT data as corresponding to saturated vapor conditions.

### 2.1.6.3 Density of Solid Hydrazine

The density of solid hydrazine can be expressed by the equation

$$\rho_s = 1.1869 - 0.000675t$$

with a maximum deviation of  $\pm 0.17\%$ , where  $\rho_s$  is the density of the solid in  $\text{g/cm}^3$  and  $t$  is the temperature in °C [113]. Unlike water, solid hydrazine does not expand as it freezes and cools off. This curve is consistent with the equation

$$\rho_L = 1.02492 - 0.000865t$$

for the density of the liquid where it overlaps, where  $\rho_L$  is the density of the liquid in  $\text{g/cm}^3$  and  $t$  is the temperature in °C.

### 2.1.6.4 Densities of Hydrazine Mixtures

#### Density of Hydrazine/Water Mixtures

The densities of hydrazine-water mixtures, or, to be accurate, hydrazine hydrate-water and hydrazine hydrate-hydrazine mixtures are of technical significance in the production of hydrazine hydrate and hydrazine and also for some applications of such mixtures as rocket propellants and gas generants. We need functions that present the density of hydrazine-water mixtures as a function of composition, temperature and maybe even pressure.

Some hydrazine/water mixture density data at 273 and 323 K and reported in the older literature [176] disagreed with later measurements and are not considered reliable data. The density of 51% and 70%  $\text{N}_2\text{H}_4$  as a function of temperature can be expressed by

$$\rho = A + BT + CT^2 + DT^3$$

where  $\rho$  is the density of the liquid in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin. The coefficients for this equation are listed in Table 8.

**Table 8:** Curve fit coefficients for hydrazine/water density equations.

Data source: Rocket Research Co. as referenced in [22]

Vapor pressure, density, and viscosity data applied to a chemical association model indicated that the hydrazine/water solutions contain a hydrazine monohydrate, a tetrahydrate, and a hydrazine dimer [170, 177]. Density data for hydrazine/water mixtures are summarized in Table 9. As illustrated in Figure 13, the density of hydrazine/water mixtures does not appear to peak exactly at a molar ratio of  $\text{H}_2\text{O}:\text{N}_2\text{H}_4 = 1:1$ , but at slightly hydrazine-rich mixtures.

Hydrazine/water mixtures are notorious for their tendency to supercool, and it is sometimes difficult to obtain exact melting points and density data near the phase-change boundary. On the other hand, density measurements of the supercooled solution provide insight into the structure of supercooled liquids [178].

In the early days of hydrazine chemistry, 82 to 98%  $\text{N}_2\text{H}_4$  was often all that was available. Using a sealed glass dilatometer, the coefficient of thermal expansion

$$\beta = \frac{1}{V_0} \frac{dV}{dt}$$

Data source: [179]

The density of hydrazine/water mixtures was measured in a range of 10 to 90 mol-%  $\text{N}_2\text{H}_4$ , at temperatures from 293 to 558 K, and at pressures from 0.1 to 58 MPa [180–184].

### Density of Hydrazine/Ammonia Mixtures

The density of hydrazine/ammonia and hydrazine/ammonia/water mixtures was already described in *Encyclopedia of Liquid Fuels* in the chapter “Ammonia.”

### Density of Hydrazine/Alkanol Mixtures

Both hydrazine(s) and alcohols are useful rocket fuels. Mixtures of hydrazine and lower alkyl alcohols have been characterized. The density of hydrazine/methanol mixtures was not truly a linear function of composition but showed a deviation in the direction toward higher than theoretical densities [185, 186]. Apparently no compound formation takes place in ethanol. This is different from the hydrazine/water system, where compound formation is documented by the nonadditive behavior of partial molar volumina and parachors. The formation of association compounds of mixtures of hydrazine with other liquids and the solution of solids in hydrazine are usually accompanied by a contraction of the volume. The maximum density occurs at a composition of a mixture that is indicative of the composition of the association compound formed in solution. The maximum volume contraction in the hydrazine-methanol system is observed at 33 mol-% hydrazine, indicative of a compound  $\text{N}_2\text{H}_4 \cdot 2\text{CH}_3\text{OH}$ . The deviation from a straight-line interpolation of densities is at a maximum at this composition.

The volume of this mixture is only 96% of that calculated from its constituents, assuming an ideal mixture. The density of hydrazine/alkanol mixtures can be expressed by

$$\rho = A + BX + CX^2 + DX^3$$

where  $\rho$  is the density (in  $\text{g/cm}^3$ ) and  $X$  is the hydrazine concentration in mass-%, and  $A$ ,  $B$ ,  $C$ , and  $D$  are constants (Table 11).

**Table 11:** Coefficients for density of hydrazine/alkanol mixtures.

| Alkanol           | A       | B                       | C                        | D                     |
|-------------------|---------|-------------------------|--------------------------|-----------------------|
| Ethanol at 298 K  | 0.78529 | $2.8642 \times 10^{-3}$ | $-6.2387 \times 10^{-6}$ | $-5.9 \times 10^{-9}$ |
| Ethanol at 313 K  | 0.77314 | $2.9479 \times 10^{-3}$ | $-6.9823 \times 10^{-6}$ | $-2.8 \times 10^{-9}$ |
| Methanol at 298 K | 0.79391 | $3.2807 \times 10^{-3}$ | $-1.9856 \times 10^{-5}$ | $8.47 \times 10^{-8}$ |

Data source: [185, 187]

### Density of Solutions in Hydrazine

The density and performance of hydrazine can be increased by dissolving energetic salts like hydrazinium nitrate in hydrazine [147, 148, 188, 189]. The properties of hydrazinium nitrate solutions in hydrazine and hydrazine/water mixtures were already summarized in *Encyclopedia of Oxidizers* in the chapter “Hydrazinium Salt Oxidizers.”

#### 2.1.7 Compressibility of Hydrazine

Rocket propellants go through changes in pressure as they pass from the propellant tank through the pumps or valves into the combustion chamber. To accurately model instability and pogo phenomena in propellant feed systems, the compressibility of the liquid fluids must be known.

The bulk modulus is the reciprocal of the coefficient of compressibility. Two types of compressibility are generally measured and reported in the literature, the isothermal and the adiabatic compressibility. The isothermal compressibility of anhydrous hydrazine and several other rocket propellants was determined by a so-called Cartesian diver method [190]. Compressibilities can also be derived from the velocity of sound [191]. Two different samples measured at 298 K had compressibilities of  $24.83 \times 10^{-6}$  and  $24.38 \times 10^{-6} \text{ cm}^2/\text{kg}_f = 2.53 \times 10^{-6}$  and  $2.48 \times 10^{-6} \text{ cm}^2/\text{N}$ . The coefficients  $10^{-6}$  were accidentally omitted in the first edition of the hydrazine book, but this mistake was corrected in the second edition.

The coefficients of thermal expansion  $\alpha$  and compressibility  $\beta$  can be calculated from partition functions based on statistical thermodynamics, which also lead to values for heat capacities at constant volume or constant pressure. Calculated results are summarized in Table 12.

**Table 12:** Compressibility of liquid hydrazine calculated from partition functions.

| Temperature, K | $\alpha \times 10^3, \text{K}^{-1}$ | $\beta \times 10^5, \text{atm}^{-1}$ | $C_v, \text{cal mol}^{-1} \text{K}^{-1}$ | $C_p, \text{cal mol}^{-1} \text{K}^{-1}$ |

| 288.15         | 0.6083                              | 0.1287                               | 14.53                                    | 20.87                                    |
| 308.15         | 0.6569                              | 0.1541                               | 14.97                                    | 21.66                                    |
| 328.15         | 0.7135                              | 0.1853                               | 15.41                                    | 22.49                                    |
| 358.15         | 0.8090                              | 0.2441                               | 16.04                                    | 23.77                                    |
| 387.3 (b.p.)   | 0.9180                              | 0.3202                               | 16.62                                    | 25.03                                    |

Data source: [192]

The compressibility of solid hydrazine is approximately  $10^{-9} \text{ m}^2/\text{N}$  ( $10^{-4} \text{ atm}^{-1}$ ) [113]. Less reliable sources report a compressibility of  $2.58 \times 10^{-10} \text{ m}^2/\text{N}$  ( $2.54 \times 10^{-5} \text{ atm}^{-1}$ ) for liquid hydrazine.

### 2.1.7.1 Adiabatic Compressibility of Hydrazine

Adiabatic compressibilities in liquids and gases can be calculated from sonic velocity data with the aid of the following equation:

$$\beta_a = \frac{1}{\rho c^2}$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{m}^2/\text{N}$ ,  $\rho$  is the density in  $\text{g}/\text{m}^3$ , and  $c$  is the velocity of sound in  $\text{m}/\text{s}$ . Using this equation to convert velocity measurements, velocity of sound measurements of anhydrous hydrazine gave an adiabatic compressibility of  $2.35 \times 10^{-5} \text{ cm}^2/\text{kg}_f = 2.39 \times 10^{-10} \text{ m}^2/\text{N}$  at 298 K (but the accuracy of this number was questioned in later publications in 2001). Data compiled by Rocketdyne over a wider temperature range (280–360 K), illustrated in Figure 14, gave the following equations for the temperature dependence of the adiabatic compressibility [193]:

$$\beta_a = 1.2742 \times 10^{-5} - 4.5295 \times 10^{-8} T + 2.7274 \times 10^{-10} T^2$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{cm}^2/\text{kg}_f = \text{atm}^{-1}$  and  $T$  is the temperature in kelvin, or in SI units:

$$\beta_a = 1.2989 \times 10^{-10} - 4.6172 \times 10^{-13} T + 2.7802 \times 10^{-15} T^2$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{m}^2/\text{N}$  and  $T$  is the temperature in kelvin. The data in Figure 14 were calculated from sonic velocity measurements.

The compressibility of hydrazine is an important physical property when it comes to calculating water hammer and surge flow pressure spikes in propellant feed systems (Section 8.8). If liquid propellant becomes trapped between two valves and experiences an increase in temperature and there are no gas bubbles in the system, then thermal expansion upon heating can cause a devastating increase in pressure. The pressure rise will be greater if the coefficient of thermal expansion is greater and the

**Figure 14:** Adiabatic compressibility of anhydrous hydrazine. (Reproduced and modified from [171].)

compressibility is smaller. Calculations of the pressure-temperature slope for liquid-locked hydrazine (held at constant volume) have been carried out on the basis of existing experimental data for isothermal and adiabatic compressibility in conjunction with thermodynamic relations [194]. The pressure-temperature slope was evaluated as the ratio of the volumetric coefficient of thermal expansion to the compressibility. The volumetric coefficient of expansion is in turn determined from the difference between the isothermal compressibility and adiabatic compressibility by a well-known thermodynamic relation. Based on these considerations, the pressure-temperature slopes were estimated for liquid-locked hydrazine components over a range of temperatures (283–323 K = 10–50 °C) of interest for propulsion applications. It was shown that the pressure-temperature slope decreases with an increase in temperature, which is contrary to the trend for water. The results indicate that the pressure rise in liquid-locked hydrazine systems is considerably higher than for water in the range of temperatures considered.

The corresponding compressibilities of hydrazine/water mixtures are presented in Figure 15. The compressibility or the velocity of sound as a function of hydrazine

**Figure 15:** Adiabatic compressibility of hydrazine/water mixtures at 298 K. (Reprinted and modified from [195], with permission of ©1955 AIP Publishing; permission conveyed through RightsLink.)

concentration shows no discontinuities like the melting-point diagram or maxima like the density and viscosity diagrams [195].

Some liquids solidify under very high pressure, and some solids undergo phase changes at very high pressure, but hydrazine monohydrate has been shown to be free of high-pressure enantiotropy and instead showed true ( $p$ ,  $T$ ) monotropy [196]. The monotropic behavior of hydrazine hydrate is well understood and extends to pressures higher than atmospheric pressure. The decomposition of hydrazine hydrate has been used as a heat source for deep-ocean power supplies, so its high-pressure behavior must be accounted for.

#### 2.1.7.2 Phase Transitions at Very High Pressures

Subjecting hydrazine in a diamond anvil to very high pressures causes new peaks to appear in its Raman spectrum. A new peak near  $3000 \text{ cm}^{-1}$  emerged above 8 GPa, indicating a new phase of hydrazine at high pressure. There were two new phase transitions near 5.5 and 8 GPa [197]. The pressure-induced changes appeared to be reversible as pressure was cycled down to 3.5 GPa.

The high-pressure behavior of hydrazine has been investigated by *in situ* Raman spectroscopy and synchrotron X-ray diffraction (XRD) experiments under pressure up to 46.5 and 33.0 GPa [198]. It was found that the liquid hydrazine solidified into phase I at about 1.2 GPa. The symmetry of phase I was confirmed to be space group  $P2_1$  by the peak assignment, group theory analysis, and Rietveld refinement of XRD patterns. A solid-solid transition from phase I to phase II was observed in both Raman spectroscopy and XRD experiments at about 2.4 GPa, which was ascribed to the formation of new hydrogen bonds between hydrazine molecules. At 18.4 GPa, an isostructural transition from phase II to the final phase III was observed.

Pressure-induced changes to the structure and bonding in hydrazine have been investigated at pressures up to 20 GPa using a diamond anvil cell with *in situ* Raman spectroscopy [199]. Liquid hydrazine solidified at 0.3 GPa into a crystalline phase, and its structure was established using synchrotron XRD measurements. The high-pressure phase is monoclinic (space group  $P2_1$ ). With increasing pressure, the modifications to N—H···N hydrogen bonding spectra were observed with the emergence of new peaks beyond 5 GPa as well as the appearance of new lattice modes. Based on these observations, it was concluded that a sluggish phase transition in the 5–7 GPa range was accompanied by selective strengthening and restructuring of the hydrogen bonding network. Inelastic neutron scattering measurements performed in the 10–250 K range indicated that the order-disorder phase transition (observed in thin films at 175–180 K) driven by conformational changes was not observed in a bulk sample. It is possible that pressure-solidified hydrazine exists along with solid ammonia at a certain depth at the bottom of the atmosphere of Jupiter.

Compressing hydrazine to very high pressures does not appear to result in the formation of new hydronitrogen compounds, such as those discussed in chapter “Hydronitrogens” in *Encyclopedia of Liquid Fuels*.

### 2.1.8 Velocity of Sound in Hydrazine

The knowledge of the velocity of sound in hydrazines is of interest in the design of rocket engine feed systems, where destructive pressure oscillations can develop and propagate upstream. Resonance phenomena must be avoided to obtain stable combustion. The velocity of sound is also useful in calculating the compressibility of hydrazine. Compressibility, in turn, is of interest in predicting the behavior of hydrazine under extremely high pressures, such as those encountered in underwater applications of hydrazine or at the bottom of ammonia-loaded planetary atmospheres.

#### 2.1.8.1 Velocity of Sound in Liquid Hydrazine

Several measurements of the velocity of sound of hydrazine have been used to calculate the adiabatic compressibilities mentioned earlier. The data varied slightly depending on the purity of the sample used; in one case, a velocity of  $2059 \pm 6$  m/s at 298 K was reported for 96%  $N_2H_4$  [191], and in another case two different samples of hydrazine gave identical sound velocities of 2090 m/s at 298 K. The dependence of the velocity of sound in anhydrous hydrazine on sample temperature can be expressed by

$$c = 3224.9 - 3.8611T$$

where  $c$  is the velocity of sound in m/s and  $T$  is the temperature in kelvin.

Sound velocities in hydrazine/water mixtures were measured as a function of composition for a large number of different concentrations of hydrazine in water from 8 to 99 mass-% of hydrazine at 298 K by means of the Debye-Sears ultrasonic light diffraction method (Figure 16) [195, 200].

**Figure 16:** Velocity of sound in hydrazine/water mixtures at 298 K. (Reprinted and modified from [195], with permission of ©1955 AIP Publishing; permission conveyed through RightsLink.)

The method used for measuring the velocity of sound is essentially like the diffraction of light by a ruled grating, except in this case the standing wave pattern of the ultrasonic waves through the liquid acts as the grating. From the known wavelength of the light source, the frequency of the quartz crystal tuned to create standing waves, and the angle of diffracted light, the distance of the standing wave nodes can be measured. The data can be represented by the equation

$$c = 1497.40 + 745.460X_H + 382.353X_H^2 - 556.3361X_H^3$$

where  $c$  is the velocity of sound in m/s and  $X_H$  is the mass fraction hydrazine in the binary mixture. For pure hydrazine ( $X = 1.00$ ), a sonic velocity of 2069 m/s was obtained by extrapolation from this equation. The velocity of sound in hydrazine is the highest of any liquid for which data are found in the literature. Likewise, this would translate into hydrazine being one of the least compressible fluids with a very high susceptibility to hydraulic shocks and pressure spikes when flowing hydrazine is abruptly stopped by the sudden closing of a valve (“water hammer”).

The velocity of ultrasound (or any sound or compression wave) in hydrazine decreases with increasing temperature (Figure 17) and increases linearly with increasing hydrazine content (tested up to 64%) [201]. The velocity of sound in liquid hydrazine at 293.15 K was measured to be  $2092 \pm 12$  m/s [202, 203], in agreement with previous measurements reported in the literature.

It is planned to determine the density of hydrazine by the buoyancy of a floater and to determine the velocity of sound in hydrazine along the saturation curve at temperatures up to the critical point and pressures up to 200 bar by measuring the resonant frequency in a high-pressure bomb made of titanium with sapphire windows [204].

**Figure 17:** Velocity of sound in anhydrous hydrazine as a function of temperature. (Reprinted and modified from [201].)

### 2.1.8.2 Velocity of Sound in Solutions of Salts in Hydrazine

Solutions of hydrazinium nitrate in hydrazine and hydrazine/water mixtures have been tested as rocket propellants and, consequently, the velocity of sound in several of such solutions has been measured. Physical property data for hydrazinium nitrate solutions in hydrazine were already described in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers.” The velocity of sound is closely related to the detonation velocities of liquid explosives. Therefore, the velocity of sound in hydrazine/hydrazinium nitrate/water ternary mixtures was measured and compared to detonation velocity data (Figure 18) [205]. See also [201].

### 2.1.9 Vapor Pressure of Hydrazine and Vapor-Phase Composition

Vapor pressure data of hydrazine and hydrazine compounds are important for the calculation of heats of vaporization and vaporization losses, the assessment of toxicity and flammability hazards, and the solution of many other technical problems. Numerous vapor pressure measurements exist, but many measurements were plagued with incipient hydrazine decomposition during measurements, feigning higher than real vapor pressures. At other times, at very low pressures, hydrazine adsorption on glass surfaces may result in erroneously low pressure readings.

**Figure 18:** Velocity of sound in ternary hydrazine/hydrazinium nitrate/water mixtures. (Reprinted and modified from [205])

### 2.1.9.1 Vapor Pressure of Pure Hydrazine

Vapor pressure measurements of hydrazine are not always accurate. In addition to differences encountered due to incipient decomposition, some early investigators had only hydrazine of insufficient purity available for their work. Some reports on vapor pressure measurements of hydrazine may have to be disregarded for this reason if the discrepancy is too large. One set of vapor pressure data of pure hydrazine could best be represented by [107]

$$\log P = 7.80687 - \frac{1680.745}{t + 227.74}$$

where  $P$  is the vapor pressure in mm Hg and  $t$  is the temperature in °C. The data of Scott 1949 are consistently higher than those previously reported [206], a fact suggesting that the earlier investigators used a sample of lesser purity. The most likely contaminant was water, which would lower the vapor pressure below that of pure hydrazine because hydrazine and water form an azeotrope. Additional vapor pressure data (over a narrower range of temperatures) agree well with those obtained by previous authors [207]. Combining three sets of data and curve-fitting by the least-squares method resulted in the following equation [171]

$$\log P = -6.50603 - \frac{653.880}{T} + 0.047914T - 4.9886 \times 10^{-5}T^2$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The normal boiling point obtained by extrapolation to 760 mm Hg from this equation is 387.37 K (114.2°C = 237.6°F). The curve shown in Figure 19 is based on this equation.

**Figure 19:** Vapor pressure of liquid anhydrous hydrazine. (Reproduced and modified from [22].)

Another vapor pressure correlation for hydrazine suggested the following equation [208]:

$$\log P = 60.003 - \frac{3880.3}{T} - 20.575 \log T + 1.5585 \times 10^{-2} T + 5.0525 \times 10^{-6} T^2$$

where  $P$  is the pressure in kPa and  $T$  is the temperature in kelvin. All previous vapor pressure determinations cover only the range below atmospheric pressure. The only vapor pressure determination above atmospheric pressure dates back two centuries and was performed by Lobry de Bruyn in 1895 [169]. It appears that during the entire 120 intervening years, nobody was daring enough to repeat these measurements at higher temperatures. These “archaic” data can be represented by

$$\log P = 4.73294 - \frac{1457.79}{T} - \frac{145452.1}{T^2}$$

where  $P$  is the pressure in atm and  $T$  is the temperature in kelvin. It is very difficult to obtain vapor pressure data above the normal boiling point and above atmospheric pressure because of incipient decomposition and the explosion hazard. It would be very desirable to repeat and verify de Bruyn's measurements with modern techniques. These data are of interest for calculating boiling phenomena in injector portions of rocket engine systems using hydrazine at high pressure. Of course, anhydrous hydrazine is no longer used in regeneratively cooled engines, but that is an area where vapor pressure at higher pressures must be known to design a system. The XLR117-NA-1 rocket engine intended for use on the NOMAD upper stage apparently was regeneratively cooled with hydrazine. It is assumed that the fuel passages were purged with inert gas after engine shutdown.

A comparison of vapor pressure data from numerous sources and presented in logarithm of reduced pressure ( $p/p_c$ ) versus inversed reduced temperature ( $T_c/T$ ) coordinates showed that most of the data fall on a straight line, many data points superimposed, with only a few outliers [105] (Figure 20).

The vapor pressure equation proposed by [173]

$$\ln P = 58.7582 - \frac{0.707 \times 10^4}{T} - 7.088 \ln T + 0.457 \times 10^{-2} T$$

**Figure 20:** Comparison of vapor pressure of hydrazine data from several sources. (Reprinted and adapted from [105], with permission from ©2001 American Chemical Society; permission conveyed through RightsLink.)

where  $P$  is the vapor pressure in atm and  $T$  is the temperature in kelvin, appeared to be the most remarkable one because it accurately reproduced (dashed line in Figure 20) the experimental data from 273 to 653 K (0 to 380 °C), that is, up to the critical point. Das and Kuloor made no measurements themselves. Their vapor pressure equation was based on data previously published in Audrieth and Ackerson-Ogg 1951 [7].

Readers are warned that the interpolating function published by Haws and Harden 1965 [172] and unfortunately repeated also on page 142 of Schmidt 1984 (first edition [11]) failed completely in reproducing the experimental data. For this reason, it was deleted from the second edition of the hydrazine book. It was also pointed out that the interpolating equation given as Equation B on page 58 of Audrieth and Ackerson-Ogg 1951 [7] suffered excessive deviations when  $T$  approached 273 K.

Unfortunately, the vapor pressure data provided by the International Critical Tables appear to be incorrect, and the source of their data could not be verified. A repeated and careful inspection of all de Bruyn's publications on hydrazine, performed in 1998, revealed no trace of such data in any of de Bruyn's publications. One must conclude, therefore, that, although the data (solid squares in Figure 20) seem to fit consistently with those of others, their origin is unknown and their experimental nature is open to doubt.

An evaluation of equation of state (EOS) and vapor pressure data led to the following equation for the vapor pressure of hydrazine [209]:

$$\log_{10} P = 60.003 - 3880.3/T - 20.575 \log_{10} T + 1.5585 \times 10^{-2} T - 5.0525 \times 10^{-6} T^2$$

where  $P$  is the vapor pressure in kPa and  $T$  is the temperature in kelvin.

At the opposite end of the temperature spectrum, there exist no good measured data on the sublimation pressure of frozen hydrazine at subfreezing temperatures, yet there may be tons of frozen hydrazine crystals in the white clouds above the ammonia clouds on Jupiter. Troublesome leaks of propellant lines in spacecraft have occasionally resulted in the formation of hydrazine icicles at the triple point when liquid hydrazine leaked into vacuum. Insufficient vapor pressure data exist to calculate the rate of hydrazine sublimation if, as the first step of problem mitigation, that part of the spacecraft was deliberately turned toward the direct sunlight to make the "hydrazinicles" disappear [111]. Another need for hydrazine evaporation data arose from the new regulations requiring that propellant tanks in idle, end-of-mission satellites, and upper stages be inerted ("passivated") to prevent tank explosions and fragmentation that would add to orbital debris (Section 7.14).

### 2.1.9.2 Equation of State of Hydrazine

The simplest equation of state (EOS) is the van der Waals equation. The van der Waals coefficients for liquid hydrazine were given as  $a = 0.846 \text{ Pa m}^6 \text{ mol}^{-2}$  and  $b = 0.0462 \times 10^{-3} \text{ m}^3/\text{mol}$ . The EOS of hydrazine was known only for near-ambient temperatures and pressures until the design of rocket cooling systems necessitated pressure-volume-temperature (PVT) data over a wide range of temperatures and pressures up to and beyond the critical point. Besides some ancient, relatively inaccessible data from 0.1 to 14.7 MPa (1.5 to 2131 psia) and 386 to 1000 K [210], no data were published for a long time until 1965. Then, using the old (very old!) vapor pressure data of de Bruyn, a Mollier diagram was calculated for hydrazine, using liquid density, heat capacity, and PVT data already available from the literature [172]. The vapor pressure equation used in this study was

$$\ln p = 24.24 - \frac{18184.9}{T} + 0.47629 \ln T - 0.003836T + \left[ \frac{1115.43(1190.08 - T)}{1190.088} \right] \ln(1190.08 - T)$$

where  $p$  is the pressure in psia and  $T$  is the temperature in °R. Comparison of this equation with experimental results revealed that the deviations never exceeded 3% and did not follow a steady pattern. The following EOS was developed for hydrazine [172] (we apologize for the use of non-SI units):

$$p = \frac{RT}{V-b} + \frac{A_2 + B_2T + C_2e^{-xT/T_c}}{(V-b)^2} + \frac{A_3 + B_3T + C_3e^{-xT/T_c}}{(V-b)^3} + \frac{A_4}{(V-b)^4} + \frac{B_5T}{(V-b)^5}$$

with  $p$  in psia,  $R$  the universal gas constant = 10.7315/mol. wt.,  $T$  in °R,  $b = 0.0299451 \text{ ft}^3/\text{lb}_m$ ,  $x = 8.0000$ ,  $T_c$  the critical temperature = 1175.69°R,  $A_2 = -32.21898$ ,  $A_3 = 0.869588$ ,  $A_4 = -0.202100 \times 10^{-1}$ ,  $B_2 = 0.00294549$ ,  $B_3 = 0.16838487 \times 10^{-3}$ ,  $B_5 = 0.12899897 \times 10^{-6}$ ,  $C_2 = -1171.2876$ , and  $C_3 = 46.250721$ . The Haws and Harden 1965 paper [172] contains severe errors for heat capacity, so all other equations from that paper will need to be critically examined for accuracy.

Mitchell [211] reexamined the Martin EOS

$$p = \frac{RT}{\underline{V}-b} + \frac{A_2 + B_2T + C_2e^{-xT/T_c}}{(\underline{V}-b)^2} + \frac{A_3 + B_3T + C_3e^{-xT/T_c}}{(\underline{V}-b)^3} + \frac{A_4}{(\underline{V}-b)^4} + \frac{B_5T}{(\underline{V}-b)^5}$$

and assigned the following constants, converted to SI units:

$$A_2 = -889.02$$

$$B_2 = 0.14629$$

$$C_2 = -32319$$

$$A_3 = 48.001$$

$$B_3 = 0.016731$$

$$C_3 = 2553.0$$

$$A_4 = -2.2317$$

$$B_5 = 5.1295 \times 10^{-5}$$

$$x = 8.0000$$

$$b = 0.059905$$

The vapor pressure equation that Mitchell erroneously credited to Giordano 2002 is actually the one published earlier by Das and Kuloor 1968 [173].

A Russian publication on the thermodynamic properties of hydrazine extended the data to the range of nonideal behavior of hydrazine vapor at high temperatures and pressures [212]. The second virial coefficient  $B$  in the EOS

$$V = \frac{RT}{p} + B$$

can be expressed by

$$B = -9.0104668 + 0.2649938 \frac{1000}{T} - 0.8832357 \frac{1000}{T^2} + 0.6849432 \frac{1000}{T^3} - 0.2101736 \frac{1000}{T^4}$$

where  $B$  is in  $\text{cm}^3/\text{mol}$  and  $T$  is the temperature in kelvin. With this equation, hydrazine vapor data can be calculated in the temperature range 300–1000 K and at pressures of up to 10 MPa. These conditions may be encountered in the injector passages of hydrazine decomposition reactors or in the periphery of burning droplets, but hydrazine will not survive very long under these conditions.

EOSs consistent with published vapor pressure data for hydrazine and MMH have been derived [208, 209, 213]. Unfortunately sets of vapor pressure and vapor and liquid heat capacity data that were available at that time from various sources were inconsistent, and it was difficult to select the most reliable set of data without repeating some of the measurements. Some of the data may have been obtained several decades ago with hydrazine of inferior purity. The Peng-Robinson and Soave-Redlich-Kwong EOSs were each validated for hydrazine and MMH using fugacity coefficient comparisons at phase equilibrium. The Peng-Robinson equation best represented hydrazine states,

and the Soave-Redlich-Kwong EOS best represented MMH states. Partial Mollier diagrams were drawn for hydrazine and MMH. These data are useful for calculating the real-gas isentropic compression temperatures in suddenly compressed vapor pockets in propulsion systems. Sudden compression of bubbles (foam) may lead to explosions.

A review of the literature as of 2005 yielded three published EOSs for hydrazine: **(1)** Martin's EOS used by Haws and Harden 1965 [172], **(2)** a modified Clausius EOS also used by Giordano and de Serio 2002 [106], and **(3)** the Peng-Robinson EOS developed by Barragan et al. 2002 [209]. The three cited works concluded that each EOS was suitable for the authors' own purposes. However, no evaluation of the three equations has been conducted for the full range of engineering design and safety analysis problems that might be encountered when using hydrazine as a rocket propellant. Therefore, an evaluation of the applicability and thermodynamic consistency of these equations for hydrazine was needed [211]. The equations were applied to the vapor-liquid phase transition using a thermodynamic consistency test comparing liquid and vapor fugacity coefficients and liquid volumes and were subjected to a test of mechanical stability. The three EOSs were all reparameterized for a consistent set of units. The vapor pressure equation from Haws and Harden 1965 was not used since it is flawed. Only the Barragan 2002 and Das-Kapoor-Giordano 2002 vapor pressure equations were used. In all cases the following parameters for hydrazine were used:  $T_c = 653$  K,  $p_c = 14700$  kPa,  $MW = 32.045$  g/mol. To calculate vapor-liquid coexistence, first a temperature  $T$  in the two-phase region was chosen. Then the corresponding vapor pressure  $p$  was calculated. With this pressure and temperature combination, the EOS was solved for the specific volume  $V$  of both the liquid and vapor, and compressibility factors  $Z$  for both phases were calculated. Equation (1) was then used to calculate the fugacity coefficient for each phase:

$$\ln \phi = \frac{1}{RT} \int_0^V \left[ p - \frac{RT}{V} \right] dV + (Z^j - 1) - \ln Z^j \quad (1)$$

When plotting the fugacity coefficients of liquid vs. fugacity coefficients of vapor for the three EOSs, where one would expect a straight line with a slope of  $45^\circ$ , only the results of the Peng-Robinson EOS calculations showed that the predicted vapor-liquid coexistence values were thermodynamically consistent, i.e., they fell on a straight line together. Neither the Martin nor the Clausius EOS produced liquid and vapor fugacities of near equivalence. This indicated some degree of thermodynamic inconsistency in these equations. While neither of these three EOSs predicted equal liquid- and vapor-phase fugacity coefficients for the entire temperature range evaluated, the Peng-Robinson EOS followed the  $45^\circ$  line more closely than the Martin EOS. From this analysis, the Peng-Robinson EOS appeared to be a superior model for predicting a wide range of thermodynamic properties of hydrazine.

In another example, the Peng-Robinson EOS was used to calculate real fluid isentropic (near adiabatic) compression temperature for hydrazine vapor/ullage gas mix-

tures [209]. The isentropic final temperature  $T_2$  after compressing an ideal gas sample from  $P_1$  to  $P_2$  is

$$T_2 = T_1 \left( \frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}}$$

where  $\gamma = C_p/C_v$ . For real gases and hydrazine vapors,  $C_p$  and  $\gamma$  vary with temperature. The EOS was inserted to calculate compression temperature as a function of compression ratio. Starting with hydrazine vapor at its room temperature vapor pressure, compression ratios beyond 200 would be required to heat the vapor to the autodecomposition temperature of hydrazine in nitrogen (about 800 K). But in air, the autoignition temperature of hydrazine would be reached with compression ratios of only 10 to 20. Similar calculations were made for helium, nitrogen, and mixtures of carbon monoxide, carbon dioxide, and water vapor in contact with hydrazine. It is assumed that the mixture of carbon monoxide, carbon dioxide, and water vapor was supposed to simulate the exhaust gas of a pyrotechnic charge in a pyro valve blow-by situation.

Most EOS computational analyses deal only with pure hydrazine. Real-life hydrazine, still in compliance with MIL-PRF specifications, may contain up to 1% water. EOS computations were performed for MIL-PRF-grade hydrazine and accounting for the contribution of a little water to the thermodynamics of the system [214]. The presence of water and other materials in MIL-SPEC hydrazine requires that thermodynamic analysis appropriate for mixtures be considered. The development of an appropriate thermodynamic description took three different approaches:

1. Using simple phase equilibrium models;
2. Using group contributions; and
3. Using new mixing rules.

Using various correlations and mixing rules, real fluid properties for hydrazine/water mixtures, as well as those containing more than 1% water, were derived and plotted. It was concluded that all three approaches chosen in this study for modeling hydrazine/water mixtures (except Raoult's law) accurately predicted vapor-liquid equilibrium at low pressures. The lessons to be drawn from this study were as follows: **(1)** an activity coefficient model will dramatically enhance a simple mixture model; **(2)** the UNIFAC model is a good predictor of hydrazine/water activity coefficients despite its intended design as a model for organic molecules; **(3)** the Peng-Robinson-Stryjek-Vera EOS is a better choice for mixtures involving water since it can predict pure water vapor pressure more accurately than the standard Peng-Robinson EOS.

### 2.1.9.3 Association in Vapor Phase

Many of the physical properties of hydrazine are due to hydrogen bonding and cluster formation in both the vapor and liquid states. The relatively high dipole moment and strong hydrogen bonding seen in IR spectra made it likely that hydrazine would be associated in the vapor phase. The association of hydrazine in the vapor phase was

already discussed in Section 2.1.6.2 on the vapor density of hydrazine vapor. There was at one point some spectroscopic evidence of hydrogen bonds in hydrazine [215]. However, early claims about dimerization of hydrazine in the vapor phase [174, 216] were proved wrong by data obtained by later investigators. Association in the vapor phase should be recognizable in the IR spectra [217]. Neither hydrazine nor 1,2-dimethylhydrazine (SDMH) or UDMH showed vapor-phase association in the range from 300 to 330 K. It was noted that hydrazine was strongly adsorbed by glass surfaces, which may account for low pressures observed by previous investigators.

Two methods exist for extrapolating unknown physical properties of chemical compounds from other known properties. One method is the so-called theorem of corresponding states, which normalizes properties by their respective critical property. The other method is the significant structure theory of liquids. The significant structure theory assumes that liquid molecules can have properties of a vapor molecule one moment and properties of a solid crystal the next. Starting with the vibrational energies of typical IR and microwave absorption bands, the rotational moments of inertia, Einstein characteristic temperature, the heat of sublimation, and the molar volume of a solid upon melting, several physical properties of liquid hydrazine, including vapor pressure between melting point and boiling point, were correctly predicted by computational methods [192]. Isotopic vapor pressure differences between  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{D}_4$  have also been explained in terms of the significant structure theory of liquids [218]. Vapor pressure differences are mainly affected by the heat of sublimation. To a lesser extent, molecular structure parameters, such as the molecular moment of inertia and the mass of isotopic molecules, also enter into the vapor pressure equation. In addition to vapor pressure, isotopic differences in molar volume, entropy, critical constants, heat capacity at constant pressure or volume, thermal coefficient of expansion, and compressibility were calculated and compared to experimental data [218].

Hydrazine in the vapor phase may form ion clusters  $(\text{N}_2\text{H}_4)_n^+$ , with  $n$  up to  $n = 5$  [219]. The structures of small hydrazine clusters from the dimer to the hexamer were calculated using a standard site-site intermolecular potential [220]. Based on these potentials, the vibrational spectra of the N—N stretching and the asymmetric  $\text{NH}_2$  wagging mode were calculated. Vibrational predissociation spectra of hydrazine  $(\text{N}_2\text{H}_4)_n$  clusters were measured from the dimer to the tetramer using a line-tunable, isotopically substituted  $\text{CO}_2$  laser [221]. The clusters were size-selected in a scattering experiment with helium atoms. These clusters can be fragmented by electron impact ionization in molecular beams [222].

Terahertz vibration-rotation-tunneling spectroscopy of the ammonia dimer has led to a debate about the structure of ammonia dimers [223]. Measurements indicated that two ammonia molecules can form a “cyclic” dimer structure instead of the traditionally assumed  $\text{N}\cdots\text{H}$  linear hydrogen bond. This new instrumental technique has not yet been applied to hydrazine vapor to determine whether dimers form there as well and what structure they might have.

*Ab initio* calculations applied to hydrazine and its dimers found five optimized stable dimers on the potential energy surface [224]. The binding energy for the most stable dimer was predicted to be  $-18$  kJ/mol. The molecular interaction slightly hinders the internal rotation. The frequencies of both the  $\text{NH}_2$  wagging mode and their blue shifts relative to those of monomer were in good agreement with experiments.

Clusters of amines, hydrazine, MMH, and UDMH may contribute to the growth of nucleation clusters in the atmosphere. Structures of the hydrazine and amine clusters containing one or two common nucleation molecules along with other pollutants have been optimized using DFT calculation methods [225]. The clusters' growth mechanism has been explored based on the thermochemistry by calculating the Gibbs free energies of adding successively an ammonia, water, methanol, or sulfuric acid molecule step by step at room temperature. The results showed that hydrazine and its derivatives could enhance heteromolecular homogeneous nucleation in Earth's or Jupiter's atmosphere. The interaction between hydrazines and ammonia is slightly stronger than that between amines and ammonia.

#### 2.1.9.4 Vapor Pressure and Vapor-Phase Composition of Hydrazine Hydrate

The vapor pressure of hydrazine hydrate and hydrazine/water mixtures is an important property for the design of hydrazine hydrate concentration/distillation facilities. The vapor pressure must be known in order to be able to evaluate the hazard from propellant spills like those of H-70 that is used as gas generant in F-16 fighter jet emergency power units (EPUs). Hydrazine hydrate behaves differently from pure liquids, as evidenced by its vapor pressure at higher temperatures. The vapor pressure in a constant-volume apparatus is higher than what would be expected without dissociation of hydrazine hydrate into hydrazine and water:

The equilibrium constant of the vapor-phase equilibrium between hydrazine and water

$$K = \frac{P_{\text{H}_2\text{O}} P_{\text{N}_2\text{H}_4}}{P_{\text{N}_2\text{H}_5\text{OH}}}$$

can be expressed by the equation

$$\log K = 8.55 - \frac{3054}{T}$$

where  $K$  is in atm and  $T$  is in K [226]. From the slope of this curve, a heat of dissociation of the vapor may be derived:  $\Delta H = 58.45 \pm 0.48$  kJ/mol ( $13.97 \pm 0.10$  kcal/mol). The entropy of dissociation in the vapor phase is  $163.6 \pm 1.6$  J mol $^{-1}$  K $^{-1}$  =  $39.1 \pm 0.4$  cal mol $^{-1}$  K $^{-1}$ .

A determination of the vapor pressure of hydrazine hydrate between 294 and 351 K gave a vapor pressure function of

$$\log p = 9.17 - \frac{2450}{T}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in K [227]. From this equation a heat of vaporization of 47.7 kJ/mol (11.4 kcal/mol) was calculated. That earlier study neglected the dissociation of hydrazine hydrate at temperatures near the boiling point. Earlier measurements had shown that hydrazine hydrate vapor at 373 K and reduced pressure is 58% dissociated [228]. At 443 K (170 °C) and atmospheric pressure, the dissociation is complete. Measurements above 456 K were hampered by incipient decomposition. Vapor pressure measurements between 300 and 393 K (27.6 and 120 °C) were curve-fitted and could be represented by the following equation [229]:

$$\log p = 0.3389 - \frac{752.5}{T} + 0.011338T$$

where  $p$  is the pressure in mm Hg and  $T$  is the temperature in K. Based on vapor density measurements in a constant-volume apparatus over the range from 343 to 423 K (70 to 150 °C), it was concluded that hydrazine hydrate vapor is completely dissociated above 343 K (70 °C). These vapor density measurements at pressures up to 67 kPa (500 mm Hg) were made in a constant-volume apparatus that was later also used for autoxidation kinetics studies.

The knowledge of the liquid-vapor phase equilibrium in the hydrazine-water system is required for the optimum design of fractionating and concentrating towers for hydrazine hydrate, a process of tremendous industrial importance. The liquid-vapor phase diagram of the hydrazine-water system was measured at five subatmospheric pressures over the entire range of compositions [230]. There are two different ways to illustrate the results. In Figure 21, the mol fraction water in the vapor is shown as a function of the mol fraction water in the liquid for one specific pressure.

For an ideal mixture of liquids, the function would be a straight line (also shown). However, as a result of the strong interaction of the two molecules with hydration, ionization, and hydrogen bonding, a significant deviation from the behavior of ideal liquids is observed. Only at one specific mixture composition, the azeotropic composition, do the two curves intersect the way they would for an ideal mixture.

From Figure 21 it can be observed that below 55 mol-% hydrazine, water will accumulate in a distillate, but its concentration in the distillate will never be less than 45 mol-%. It is noteworthy that for all pressures investigated, the azeotropic composition does not coincide with the theoretical composition of hydrazine hydrate (50 mol-%). Instead, the azeotrope always occurs on the hydrazine-rich side of the stoichiometric composition. The dependence of the azeotropic composition on pressure is sum-

marized in Table 13. Based on these data, it is impossible to concentrate hydrazine to more than 55.5 mol-% (69 mass-%)  $\text{N}_2\text{H}_4$  by simple single-stage distillation.

Figure 22 illustrates the same data as shown in Figure 21 in slightly different form. From this diagram one can read the composition of the liquid and vapor phase formed if a given vapor sample is allowed to cool off and condense progressively.

**Figure 22:** Boiling point as a function of composition for hydrazine-water system. (Reprinted and modified from [230], with permission from ©1952 American Chemical Society; permission conveyed through RightsLink.)

Extrapolation of data indicates a boiling point of 386.9 K (113.8°C) for pure hydrazine at 101 kPa (760 mm Hg). The boiling point of the azeotrope at the same pressure is approximately 393 K (120°C).

A similar, but more detailed, investigation of the vapor-liquid equilibrium in the hydrazine-water system was based on more data points (25 points) than the previous set, and the data were taken at exactly atmospheric pressure (760 mm Hg) [231]. The maximum boiling azeotrope boiled at 393.2 K (120.1°C = 248.2°F) and had a composition of 58.5 mol-% hydrazine. It was confirmed that it is not possible to completely dehydrate hydrazine by a straight distillation process. It is possible, however, to concentrate hydrazine solutions to approximately 69 mass-% hydrazine by distillation at atmospheric pressure. Concentrations beyond 70% can be achieved only by azeotropic distillation with an auxiliary fluid.

The azeotrope found by other authors was at 52.7 mol-% (66.6 mass-%) hydrazine, and its boiling point was at 760 mm Hg of 393.3 K (120.2°C) [232]. Extrapolating to 100% hydrazine, these authors cited a boiling point of 387.6 K (114.5°C) for pure hydrazine.

Another study measured the equilibrium compositions of the liquid and vapor phases at reduced pressures from 2.67 to 101 kPa (20 to 760 mm Hg) [233]. A change in pressure had only a very slight effect on the vapor-liquid equilibrium. The activity coefficients of the components were determined experimentally and compared to theoretical results derived from the Van Laar equation. Equilibrium data of the liquid-vapor system can also be used to calculate the heat of mixing of hydrazine and water in the liquid phase [234].

The equilibrium vapor pressure of hydrazine, MMH, or UDMH above dilute aqueous solutions is important in predicting the efficiency of packed-bed wet scrubbers for the removal of hydrazines from pressurization gases vented from propellant tanks to the atmosphere [235]. The activity coefficient of hydrazine  $\gamma_a$  in water can be calculated from

$$\log \gamma_a = \frac{-1.0680}{\left[1 + \frac{1.0680X_a}{0.5410(1-X_a)}\right]^2}$$

where  $X_a$  is the hydrazine mol fraction in the liquid phase. Initially,  $\text{N}_2\text{H}_5\text{OH}/\text{H}_2\text{O}$  vapor-phase composition data were available only for the temperature range 329–385 K. Measurements of the  $\text{N}_2\text{H}_4$  partial pressure in the vapor phase above 35, 54.4, and 64% solutions of  $\text{N}_2\text{H}_4$  in  $\text{H}_2\text{O}$  expanded the range of measured data and agreed well with extrapolated data [236]. See also [237].

The vapor-phase composition measurements by Wilson, Munger, and Clegg [231] were reevaluated by Ferriol 1993 and illustrated in Figure 3 on page 293 of that publication [238]. Predictions for hydrazine-water isobaric vapor-liquid equilibria and vapor-phase compositions from quantum-mechanical and grand equilibrium and force field model computational methods were compared to measured data from Uchida or de Bruyn and were in moderately accurate agreement [239, 240].

Anhydrous hydrazine has a high affinity to moisture from the atmosphere, forming hydrazine hydrate. The hygroscopicity of hydrazine and the rate of water absorption were illustrated by spreading 25 mL anhydrous hydrazine in a Petri dish with a surface area of  $16.3\text{ cm}^2$ . The water content increased to 50% within 4 d [241]. The initial rate of water absorption was 90 ppm  $\text{H}_2\text{O}/\text{min}$  at 30% relative humidity (RH), 295 K, and 829 mbar (Denver). At the same time, substantial amounts of carbon dioxide were absorbed from atmospheric air.

#### 2.1.9.5 Vapor Pressure of Hydrazine Mixtures

The vapor pressures of hydrazine mixtures with ammonia were already described in the chapter on ammonia, including ternary mixtures containing hydrazine, ammonia, and water. Vapor pressures of mixtures of hydrazine with MMH or UDMH will be described in the chapters “Methylhydrazine” and “Dimethylhydrazines.”

#### 2.1.9.6 Vapor Pressure of Salt Solutions in Hydrazine

The one salt solution in hydrazine that is of particular interest as a rocket propellant is the solution of hydrazinium nitrate in hydrazine. Vapor pressures of ternary  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$  mixtures, candidate liquid gun propellants, were first determined by heating the solutions to boiling temperature in a boiling refluxing dynamic system where a certain amount of decomposition was inevitable [242]. This slight decomposition had the effect of raising the pressure above the liquid, such that

temperature-pressure data pairs had to be read rapidly without too much time passing. The vapor pressure can be calculated from

$$\log p = A - \frac{B}{T}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in K. The coefficients  $A$  and  $B$  were obtained by curve-fitting numerical data from various sources and are compiled in Table 14.

**Table 14:** Vapor-pressure equation coefficients for hydrazine/hydrazinium nitrate/water solutions.

| Composition (mass-%) <sup>a</sup> |                                               |                  | Range, K | Coefficients |         | References |

<sup>a</sup> Numbers do not add up to 100%. Balance is assumed to be aniline and/or ammonia.

The vapor pressure of a 24% hydrazinium nitrate solution in hydrazine between 334.6 K/10 kPa and 452.6 K/752 kPa can be expressed by the following curve-fitting equation [244]:

$$\log p = 9.097817 - \frac{2446.4543}{T}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in K. Vapor pressure data of hydrazinium azide solutions in hydrazine, hydrazine/ammonia, and hydrazine/water solvents were reported in [150] and [151].

### 2.1.10 Viscosity of Hydrazine

There are two common definitions of viscosity in use. The absolute (dynamic) viscosity  $\mu$  is defined as the force per unit area necessary to maintain a unit velocity gradient

at right angles to the direction of flow between two plates a unit distance apart; the SI unit for absolute viscosity is Pa s or N s m<sup>-2</sup>. The kinematic viscosity  $\sigma$  is defined by

$$\sigma = \frac{\mu}{\rho}$$

where  $\rho$  is the density of the incompressible fluid. The common unit for dynamic viscosity is centipoise (cP or cPs), 1 cPs = 10<sup>-3</sup> N s/m<sup>2</sup>. The common unit for kinematic viscosity is centistokes (cSt), 1 cSt = 10<sup>-6</sup> m<sup>2</sup>/s. Kinematic viscosity data can be converted back to dynamic viscosity by multiplying by the density:  $\mu = \sigma \times \rho$ .

### 2.1.10.1 Viscosity of Pure Hydrazine

The viscosity of liquid hydrazine and the methylhydrazines has been measured by numerous investigators as a function of temperature (Table 15).

**Table 15:** Viscosity of anhydrous hydrazine at 101 kPa.

| Temperature |       | Absolute viscosity | Kinematic viscosity | References |
|-------------|-------|--------------------|---------------------|------------|
| K           | °C    | cPs                | cSt                 |            |
| 288.16      | 15.0  | 1.0159             | 1.0225              | [166]      |
| 310.94      | 37.8  | 0.7316             | 0.7268              |            |
| 338.72      | 65.6  | 0.5399             | 0.5363              |            |
| 366.49      | 93.3  | 0.4286             | 0.4028              |            |
| 394.27      | 121.1 | 0.3578             | 0.3266              |            |
| 422.05      | 148.9 | 0.3081             | 0.2728              |            |
| 449.83      | 176.7 | 0.2733             | 0.2344              |            |
| 274.2       | 1.1   | 1.293              | —                   | [168]      |
| 275.2       | 2.1   | 1.272              | —                   |            |
| 276.2       | 3.1   | 1.251              | —                   |            |
| 278.2       | 5.1   | 1.207              | —                   |            |
| 283.2       | 10.1  | 1.118              | —                   |            |
| 288.2       | 15.1  | 1.044              | —                   |            |
| 293.2       | 20.1  | 0.9736             | —                   |            |
| 298.2       | 25.1  | 0.9049             | —                   |            |
| 298.2       | 25.1  | 0.9031             | —                   | [245]      |
| 323.2       | 50.1  | 0.6731             | —                   |            |
| 298.1       | 25    | 0.894              | —                   | [187]      |
| 313.1       | 40    | 0.727              | —                   |            |

The viscosity of hydrazine itself has even been measured as a function of pressure at pressures up to 25.25 MPa (250 atm) (Table 16). There are few viscosity data at temperatures above 360 K, where hydrazine begins to decompose.

**Table 16:** Absolute viscosity of hydrazine at elevated pressure.

| Temperature, K | Viscosity, cPs   |               |       |       |       |       |
|----------------|------------------|---------------|-------|-------|-------|-------|
|                | At boiling point | Pressure, MPa |       |       |       |       |
|                |                  | 5.05          | 10.1  | 15.15 | 20.2  | 25.25 |

Data source: [246]

The viscosity data by several authors can be represented by the following least-squares-fit equation:

$$\log \mu = 3.1788 - 0.015384T + 1.5395 \times 10^{-5} T^2$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. A smoothed curve calculated with this equation is shown in Figure 23.

Taking the data by Ahlert, Bauerle, and Lecce [166] only, a more accurate correlation by least-squares fit is represented by the equation

$$\ln \sigma = -2.4830 + \frac{404.28}{T} + \frac{2.6197 \times 10^6}{T^3}$$

where  $\sigma = \mu/\rho$  is the kinematic viscosity in centistokes. Earlier, Walden and Hilgert [168] had expressed their dynamic viscosity data by means of the slightly simpler equation

$$\log \mu = \frac{536}{T} - 3.844$$

where  $\mu$  is the dynamic viscosity in  $\text{dyn scm}^{-2}$ , and  $T$  is the temperature in kelvin. Hydrazine is one of the few fluids for which viscosity is known as a function of not only temperature, but also pressure. The pressure dependence of hydrazine viscosity has been determined at pressures up to 25.25 MPa (250 atm) [246]. The data are tabulated in Table 16, and the highest pressure data are superimposed on the curve shown in Figure 23. The viscosity increases with increased pressure because the molecules are forced in a more regular arrangement where intermolecular forces (hydrogen bonding and van der Waals forces) become more effective. The increase is more pronounced at higher temperatures than at lower temperatures. Thus, at 353 K, the increase is almost

**Figure 23:** Absolute viscosity as a function of temperature for liquid anhydrous hydrazine. (Reproduced and modified from [171].)

10% when the pressure is increased from 0.1 to 25 MPa. At ambient temperature, the increase is only 3%. For most ordinary applications, the variation of viscosity with pressure may be neglected. When designing a feed system for deep-sea application of hydrazine, however, the pressure variation may have to be considered.

There are no measured data for the viscosity of hydrazine vapor, but extrapolated, theoretical data show hydrazine vapor viscosity increasing linearly from 80 micropoise at 273 K to 130 micropoise at 448 K [101]. Data beyond 500 K are meaningless because hydrazine vapor would not be stable under those conditions.

#### 2.1.10.2 Viscosity of Hydrazine/Water Mixtures

The viscosity of hydrazine/water mixtures indicates compound and hydrate formation at specific molecular ratios. Vapor pressure, density, and viscosity data applied to a chemical association model in the hydrazine-water system indicated that the solutions contain a hydrazine monohydrate, a tetrahydrate, and a hydrazine dimer [170, 177]. Viscosity data for hydrazine/water mixtures are summarized in Table 17. As illustrated in Figure 24, the viscosity of hydrazine-water mixtures does not appear to peak exactly at a molar ratio of  $\text{H}_2\text{O} : \text{N}_2\text{H}_4 = 1 : 1$ , but in slightly hydrazine-lean mixtures.

**Table 17:** Dynamic viscosity of hydrazine/water mixtures.

| Temperature, K                             | 293.15         | 278.15 | 268.15 | 258.15 | 248.15 |

**Figure 24:** Dynamic viscosity of hydrazine/water mixtures. (Image created by Schmidt 2020 based on data from [170])

The kinematic viscosity of hydrazine/water mixtures as a function of temperature can be expressed by a polynomial equation:

$$\log \sigma = A + BT + CT^2 + DT^3$$

where  $\sigma$  is the kinematic viscosity in cSt and  $T$  is the temperature in kelvin and the coefficients A, B, C, and D are given in the following Table 18 for two different hydrazine concentrations:

**Table 18:** Coefficients for viscosity equation of hydrazine/water blends.

| Mass-% $\text{N}_2\text{H}_4$ | A       | B        | C                        | D                         |
|-------------------------------|---------|----------|--------------------------|---------------------------|
| 51                            | 40.6521 | -0.38006 | $1.21463 \times 10^{-3}$ | $-1.32110 \times 10^{-6}$ |
| 70                            | 33.8633 | -0.30279 | $9.19117 \times 10^{-4}$ | $-9.45536 \times 10^{-7}$ |

Data source: Rocket Research Co. as referenced in [22]

The density and dynamic viscosity of hydrazine/water mixtures in a range from 10 to 90 mol-%  $\text{N}_2\text{H}_4$ , at temperatures from 293 to 558 K, and at pressures from 0.1 to 58 MPa were measured [180–183, 247]. See also [248].

### 2.1.10.3 Viscosity of Hydrazine/Ammonia Mixtures

The viscosity of hydrazine-ammonia and hydrazine/ammonia-water mixtures was already described in the chapter “Ammonia.”

### 2.1.10.4 Viscosity of Hydrazine/Alcohol Mixtures

The kinematic viscosity of hydrazine/methanol mixtures listed in Table 19 shows a maximum at 40% hydrazine, close to the composition of a molar ratio hydrazine: methanol = 2 adduct for which other extremes of physical properties had been observed [185, 186].

The kinematic viscosity of hydrazine/methanol mixtures as a function of hydrazine concentration can be expressed by

$$\sigma = 0.7541 + 0.02742X - 4.4918 \times 10^{-4}X^2 + 1.9658 \times 10^{-6}X^3$$

where  $X$  = mass-%  $\text{N}_2\text{H}_4$  and  $\sigma$  = kinematic viscosity (cSt). The viscosity of hydrazine/ethanol mixtures also passes through a maximum at 60 mol-% (68.3 mass-%) hydrazine [187]. This corresponds to a  $\text{N}_2\text{H}_4:\text{C}_2\text{H}_5\text{OH}$  molar ratio of 1.5:1. Whereas density data did not indicate any compound formation between hydrazine and ethanol, there appears to be strong hydrogen bonding in  $\text{N}_2\text{H}_4/\text{C}_2\text{H}_5\text{OH}$  mixtures. Hydrazine/water and hydrazine/ethanol mixtures are notorious for their tendency to supercool, and it is sometimes difficult to obtain exact melting points and density data near the phase-change boundary. On the other hand, viscosity measurements of supercooled solutions provide insight into the structure of supercooled liquids [249]. The addition of hydrazine tends to diminish any anomalous increase in the viscosity of supercooled water, an effect like that seen in other types of measurements. Addition to ethanol, on the other hand, enhanced viscosity.

**Table 19:** Viscosity of hydrazine/alcohol mixtures.

### 2.1.10.5 Viscosity of Hydrazine/MMH and Hydrazine/UDMH Mixtures

The viscosities of hydrazine/MMH and hydrazine/UDMH mixtures will be described in *Encyclopedia of Liquid Fuels* chapters “Methylhydrazine” and “Dimethylhydrazines.”

### 2.1.10.6 Viscosity of Salt Solutions in Hydrazine

The viscosities of solutions of hydrazinium nitrate in hydrazine and hydrazine/water mixtures were already described in *Encyclopedia of Oxidizers* in the chapter on hydrazinium salts. Similar data are available for solutions of hydrazinium azide in hydrazine.

### 2.1.11 Surface Tension of Hydrazine

Knowledge of the surface tension of hydrazine and its derivatives is of both theoretical and practical interest because (1) the surface tension can be used to derive parachor data and obtain information on the molecular structure and association of molecules of these compounds and (2) the design of fuel tanks for retaining fluids by capillary forces in the weightlessness of outer space requires knowledge of the surface tension and wetting angles.

The surface tension of hydrazine as a function of temperature in a range of 294 to 313 K has been measured using the bubble method, also in comparison to that of water [250–253]. In addition to multi-point determinations, single-point surface tension determinations have been reported by other authors, as summarized in Table 20.

**Table 20:** Surface tension of hydrazine.

| Temperature |       | Surface tension, dyn/cm <sup>a</sup> |                  |          | References |
|-------------|-------|--------------------------------------|------------------|----------|------------|

| 25          | 298   | 65.954                               | —                | —        | [187]      |
| 40          | 313   | 53.165                               | —                | —        |            |
| 25          | 298   | 66.67                                | —                | —        | [167]      |
| 35          | 308   | 62.32                                | —                | —        | [256]      |

<sup>a</sup> 1 dyn/cm equals  $10^{-3}$  N/m

Of these, only Baker's data [256] agree with Bernard's [252] curve. Using only these two sets of data points, the surface tension of hydrazine as a function of temperature can be described by a linear equation, also illustrated in Figure 25:

$$\gamma = 0.139903 - 0.24637 \times 10^{-3} T$$

where  $\gamma$  is the surface tension in N/m and  $T$  is the temperature in kelvin. The surface tension at 298 K is 0.06645 N/m.

**Figure 25:** Surface tension of anhydrous hydrazine. (Reproduced and modified from [171].)

The parachor, a dimensionless number, is an atomic characteristic that enables one to calculate the surface tension of liquids if the molecular mass (weight), the liquid density, and the vapor density are known. The parachors contributed by individual atoms are additive. Adding up atomic parachors of  $2 \times 12.5$  for nitrogen and  $4 \times 17.1$  for hydrogen reported in the literature [257], one obtains a parachor sum of 93.4, whereas above surface tension gives 91.2, in close agreement when entered into the following equation:

$$P = \frac{M\gamma^{\frac{1}{4}}}{\rho_1 - \rho_v}$$

where  $M$  is the molecular mass,  $\rho_1$  is the liquid density, and  $\rho_v$  is vapor density. The surface tension of liquids decreases with increasing temperature, and it should be equal to zero at the critical temperature. Extrapolation of the Razouk data represented by the equation

$$\gamma = 1.291 \times 10^5 \left(1 - \frac{T}{632}\right) \quad (\gamma = \text{N/m}; T = \text{K})$$

to  $\gamma = 0$  would give a critical temperature of 632 K. This is in fair agreement with the critical temperature determined by other methods (653 K). See also [258].

### 2.1.11.1 Wetting Angle of Hydrazine on Metal Surfaces

Whereas there are numerous data on hydrazine viscosity and surface tension, only very little data can be found on the angle of wetting of hydrazine in contact with various surfaces. Such wetting angle data are needed for the design of surface tension retention propellant management devices in hydrazine tanks for space use in zero-gravity environments (Section 6.8). The wetting angle is largely dependent not only on the chemical composition of the metal but also on the method of surface treatment prior to testing and on surface changes that may occur with prolonged wetting by hydrazine or exposure to hydrazine vapor. Measurements at Société d'Etude de Propulsion (SEP) in France [259] showed a wetting angle of 25–45° (mostly 40–45°) for hydrazine on titanium with a hysteresis of approximately 5°, whereas previous investigators had reported wetting angles of 0–2° for most materials studied (Harris Research Laboratory, no further information given).

### 2.1.11.2 Surface Tension of Hydrazine/Water Mixtures

The surface tension of hydrazine hydrate and numerous hydrazine/water mixtures has been measured, and the results summarized in Table 21 show a maximum at 30–33 mol-%  $\text{N}_2\text{H}_4$ . This is quite unusual, since other physical properties of the hydrazine-water system, such as density, viscosity, or melting point, show extreme values at 50 mol-%  $\text{N}_2\text{H}_4$ , corresponding to  $\text{N}_2\text{H}_5\text{OH}$ .

**Table 21:** Surface tension of hydrazine/water mixtures at 298 K.

| Hydrazine concentration |        | Surface tension     |
|-------------------------|--------|---------------------|
| Mol-%                   | Mass-% | dyn/cm <sup>a</sup> |
| 0.0                     | 0.0    | 71.96               |

Data source: [256]

Hydrazine, like water, forms hydrogen-bonded clusters in the liquid phase. The surface tension of hydrazine and water mixed together, forming hydrazine hydrate and new types of clusters, shows a highly unusual behavior not seen with other liquids [260].

### 2.1.11.3 Surface Tension of Hydrazine/Ethanol Mixtures

The addition of alcohols instead of water to hydrazine partially breaks up the hydrogen-bonded associated clusters and lowers the viscosity [261]. The surface tension of hydrazine/ethanol mixtures increases with hydrazine content (Table 22), but there is an abrupt increase in surface tension as the hydrazine concentration approaches 100%.

**Table 22:** Surface tension of hydrazine/ethanol mixtures.

| Composition, Hydrazine |       | Surface tension, dyn/cm at |         |
|------------------------|-------|----------------------------|---------|

### 2.1.11.4 Surface Tension of Solutions of Hydrazinium Salts in Hydrazine

The surface tension of solutions of hydrazinium nitrate in hydrazine was already described in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers.”

### 2.1.12 Pressurant Gas Solubility in Hydrazine

The solubility of gases in hydrazine(s) is of special interest in the application of hydrazine(s) as rocket propellants. In many cases the propellants are fed into the decomposition or combustion chamber by a pressurant gas, usually nitrogen or helium [262]. Unless a gastight, impermeable diaphragm is used, the fuels become saturated with the pressurant gas. The heat-transfer characteristics of gas-saturated liquids are significantly different from those of pure liquid because dissolved gas bubbles are released prematurely, blocking effective heat transfer and sometimes

causing the rocket chamber wall to burn out. Release of dissolved gases and loss of thermal margin causes two-phase flow. Two-phase flow has a higher pressure drop than clean single-phase flow. In other cases, the release of gas bubbles may cause thrust anomalies of rocket engines fed with two-phase propellant. An arcjet may extinguish if gas bubbles pass through the gas generator. Multitudes of gas bubbles (foam) make hydrazine more sensitive to explosion by adiabatic compression. Solubility-pressure relationships are governed by Henry's law

$$\chi = KP$$

where  $\chi$  is the mol fraction of dissolved gas,  $P$  is the partial pressure of the gas, and  $K$  is the solubility constant, or, rather, coefficient. If the pressure is entered in units of atmospheres, then the unit of  $K$  is  $\text{atm}^{-1}$ .

Henry's law describes the maximum amount of pressurant gas that can dissolve in a liquid under equilibrium conditions. The law states that at a constant temperature the concentration of a gas in the liquid phase is proportional to the partial pressure of the dissolving gas in the gas phase:

$$P_g = \chi_g \times k_{H,p,c} = N_{\text{gas}}/N_{\text{solvent}} \times k_{H,p,c}$$

where  $P_g$  is the partial pressure of the dissolving gas in the gas phase,  $\chi_g$  is the mol fraction of dissolved gas,  $k_{H,p,c}$  is Henry's constant (coefficient) in the dimension of  $\text{atm L/mol}$ , and  $N_{\text{gas}}$  and  $N_{\text{solvent}}$  are the number of mols in the saturated solution.

In reality, the variation of the partial pressure of a gas is never completely linear with the variation of the mol fraction  $\chi_g$  of gas in the liquid phase, especially when it is considered over the entire concentration range from  $\chi_g = 0$  to  $\chi_g = 1$ . Nevertheless, for low concentrations of gas in the liquid phase, when  $\chi_g < 0.01$ , the variation of mol fractions usually fit a linear relation within experimental error.

Because several forms of equations are used to express Henry's law, and all  $k_H$  may be referred to as Henry's law constants, readers of the technical literature must be quite careful to verify which version of the equation is being used because the constant will have different numbers and different units.

Henry's constant varies with temperature, which is why it would be better to call it Henry's *coefficient* instead of Henry's *constant*. Depending on the gas and the solvent, solubility can increase or decrease with increasing temperature. In a closed vessel with liquid at the bottom and gas in the ullage, when the temperature increases, **(1)** the density of the liquid propellant decreases, which leads to a smaller ullage volume and compression of the ullage volume gases. In addition, **(2)** the vapor pressure of the propellant increases, and in some cases, **(3)** the gas solubility increases. In tanks with a small ullage volume fraction the effects of **(1)** and **(3)** are accentuated.

The solubility of common pressurant gases (nitrogen, argon, helium) in hydrazine in the form of  $K$  as a function of temperature can be read from Figure 26, but these data were obtained only at very low pressure and were later shown to be inconsistent with

**Figure 26:** Gas solubility in liquid  $\text{N}_2\text{H}_4$  as a function of temperature at low pressure. (Chart created by Schmidt 2000, based on data from [263])

high pressure data. The newer data exhibited solubilities about half of what is shown in Figure 26.

The unit of  $K$  in this image is  $\text{atm}^{-1}$ . Most of the pressurant gas solubility data are from [263–265]. Similar data are available for methylhydrazines. For several decades, these were the only gas solubility data available in the open literature. These experiments were conducted in glass bulbs over a pressure range of 110 to 234 kPa (16 to 34 psia). The previous testing was limited due to the difficulties in conducting high-pressure experiments in glass bulb test apparatus. Although this pressure range is close to the pressure used during propellant filling on the ground, it is much lower than typical operating pressures of 1.38 to 2.8 MPa (200 to 400 psia) in satellites. Henry's law is obeyed for dilute solutions; thus, these older data should theoretically scale with pressure. However, there is considerable uncertainty involved in extrapolating data with 25% uncertainty an order of magnitude above its measured pressure range. The measured values for the mol fraction of helium at 293.16 K were  $0.52 \times 10^{-5}$  at 110 kPa and  $1.10 \times 10^{-5}$  at 234 kPa.

Attempts have been made to derive gas solubility for binary mixtures of hydrazine and UDMH from statistical thermodynamic considerations [266]. Henry's law constant

for the solubility of different gases in liquid hydrazine, MMH, and UDMH was computed from force field models [240].

Extending gas solubility measurements to higher pressures, the solubility of helium in hydrazine starting at 3.4 and 6.9 MPa (500 and 1000 psia) was measured by connecting thermostatted Teflon-lined stainless-steel cylinders of known volumes and observing the decay of pressure as the gas dissolved in the liquid, with different amounts of hydrazine loaded to vary the ullage, and with and without agitation of the liquid [267]. The accuracy of the apparatus and method was confirmed by measuring the solubility of helium in water and comparing the results to well-known literature data for water, also included in Figure 27 for comparison. Argon is more soluble in hydrazine than nitrogen and nitrogen is more soluble than helium.

**Figure 27:** Measured mol fractions of gases in hydrazine as a function of gas pressure at high pressure at 293 K. (Reproduced and modified from [267]. Courtesy of and reprinted by permission of The Aerospace Corporation, granted 11 May 2021.)

The observed difference between the recent results and previous experiments can be discussed in terms of the equilibrium constant. The previous equilibrium constant [263–265] for helium dissolved in hydrazine was reported to be  $k_{\text{He}} = 5.0 \pm 1.0 \times 10^{-6} \text{ atm}^{-1}$ . The more recent determination was  $k_{\text{He}} = 2.60 \pm 0.35 \times 10^{-6} \text{ atm}^{-1}$  at 293.15 K. This value is about half (0.52) the previously measured value.

A small amount (5%) of water was added to hydrazine in recent experiments to test the effects of water content on helium solubility in an effort to explain the difference between the 1968 and 2015 data. Figure 6 of [267] shows the effect on the mol fraction of

helium as a result of increasing the water content of the hydrazine. The small change in water content did not greatly affect the measured mol fraction beyond the current scatter in the data. The purity of the hydrazine is not a likely source of the discrepancy between the 1968 and 2015 data.

It is interesting to note that in the case of hydrazine, the solubility of all three gases, helium, argon, and nitrogen, increases with temperature (Figure 28). This is different from the solubility behavior of other gases in other liquids.

**Figure 28:** Pressure dependence of the mol fraction for helium in hydrazine at three different temperatures. (Reproduced and modified from [267]. Courtesy of and reprinted by permission of The Aerospace Corporation, granted 11-May-2021.)

The equilibrium constants for argon and nitrogen in hydrazine were also found to be outside two standard deviations of the reference [263–265] results ( $k_{\text{Ar}} = 10.4 \pm 0.9 \times 10^{-6} \text{ atm}^{-1}$  at 293.15 K compared to the old value of  $k_{\text{Ar}} = 11.6 \pm 0.8 \times 10^{-6} \text{ atm}^{-1}$ ; and  $k_{\text{N}_2} = 5.13 \pm 0.78 \times 10^{-6} \text{ atm}^{-1}$  at 293.15 K compared to the old value of  $k_{\text{N}_2} = 6.9 \pm 0.4 \times 10^{-6} \text{ atm}^{-1}$  [267]).

It would be desirable to have a portable analytical instrument that could determine the propellant gas saturation level (like oxygen saturation in human blood) at launch sites where satellites are fueled. The method should also be capable of telling the difference between helium and other dissolved gases. There is always a small amount of nitrogen dissolved in hydrazine as a result of its slow decomposition during storage. Helium solubility in hydrazine at 295 K and 1786 kPa (245 psig) measured by a gas chromatographic technique was approximately 45% lower than previously published values [268]. There was significant scatter in five identical samples analyzed consecutively. The average of five measured values was 6.1 ppm (where ppm is the mass of helium/mass of propellant), whereas most other

publications reported 11.3 ppm. The scatter may be due to problems with reproducibly sampling saturated liquids under pressure. Hydrazine was saturated by sparging for 3 h at 295 K and 1786 kPa and allowing it to stand for 12 h to equilibrate. Samples taken after longer sparging times showed no further increase in saturation.

A gas chromatographic method was used to analyze dissolved helium in hydrazine and determine the time required to achieve saturation in stagnant (non-stirred) tanks loaded with hydrazine [269]. The time to achieve saturation at 482 kPa (70 psia) was 5 h.

Another purely mechanical method for determining the degree of helium saturation in hydrazine is to take a sample into an evacuated cylinder of known volume, seal it off, then connect its vapor space to another evacuated cylinder with a known volume, and measure the pressure after the two cylinders have equilibrated [270].

After a series of upper-stage explosions that scattered orbital debris, it has become a requirement to dump all residual propellant at the end of a mission and inert (passivate) the tanks by exposing them to the vacuum of space. The rate at which liquid hydrazine will escape once the drain valve is opened will depend on the degree of pressurant gas saturation [271]. Suddenly opening the drain valve is like opening a champagne bottle with too much fizz that has not been precooled. Some, but not all, of the liquid will be ejected along with the released gas.

Another important parameter involved in the mechanism of helium dissolving into hydrazine is the diffusion coefficient of the gas into the hydrazine liquid. This number has not previously been measured in the open literature. New experiments have attempted to measure this number for the first time [267]. The solubility was measured by determining the pressure drop in a closed stainless-steel bulb using pressure capacitance manometers. The pressure drop in a stirred bulb was used to determine the solubility, whereas the pressure drop in an unstirred bulb was used to determine the diffusion coefficient.

### 2.1.13 Thermal Conductivity of Hydrazine

#### 2.1.13.1 Thermal Conductivity of Solid Hydrazine

The thermal conductivity of solid hydrazine as expressed by the equation

$$\frac{dQ}{dt} = -Ak_s \frac{\delta T}{\delta x}$$

was measured as the temperature differential on a slab of frozen hydrazine with a surface area of  $A = 62.07 \text{ cm}^2$  and a thickness of 1.27 cm and calculated as  $k_s = 1.569 \times 10^{-1} \text{ W m}^{-1} \text{ K}^{-1} = 3.750 \times 10^{-3} \text{ cal s}^{-1} \text{ cm}^{-1} \text{ }^\circ\text{C}^{-1} = 2.520 \times 10^{-4} \text{ BTU s}^{-1} \text{ ft}^{-1} \text{ }^\circ\text{F}^{-1}$  [272].

#### 2.1.13.2 Thermal Conductivity of Liquid Hydrazine

No experimental data have been published so far on the thermal conductivity of liquid hydrazine for a wide range of temperatures. A polynomial equation for calculating

thermal conductivity was found in a second-hand source, but no details were given as to how this equation was obtained [273]:

$$\lambda = 2.1067 \times 10^{-4} + 6.5541 \times 10^{-6}T - 1.1179 \times 10^{-8}T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. The curve illustrated in Figure 29 is only based on approximate data and not very accurate. We hesitated to include such preliminary data in this book, but more accurate data could not be found.

**Figure 29:** Thermal conductivity of liquid hydrazine. (Reproduced and modified from [171].)

Liquid thermal conductivity for hydrazine was estimated by means of a modified Schaeffer and Thodos correlation

$$k_L = k_c q(\text{Tr}, \text{Pr})$$

where  $k_c$  represents critical thermal conductivity and  $q(\text{Tr}, \text{Pr})$  is a functional relationship available from tables [102]. According to these data, the liquid thermal conductivity of hydrazine drops nearly linearly from  $2.2 \times 10^{-3} \text{ cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$  at 273 K to  $9 \times 10^{-4} \text{ cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$  at 520 K.

A single data point of  $0.50 \text{ W m}^{-1} \text{ K}^{-1}$  ( $0.29 \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ }^{\circ}\text{F}^{-1}$ ) at  $293 \text{ K}$  referenced from another second-hand source was found in an old Jet Propulsion Laboratory (JPL) report [274]. The thermal conductivity of liquid hydrazine/methanol mixtures has also been measured [185, 186]. A thermal conductivity of  $5.4 \times 10^{-1} \text{ W m}^{-1} \text{ K}^{-1}$  ( $1.3 \times 10^{-3} \text{ cal }^{\circ}\text{C}^{-1} \text{ cm}^{-1}$ ) was measured for pure hydrazine in this series. This number is much higher than data reported by other sources.

The thermal conductivity of liquid hydrazine was measured by a steady-state hot-wire method at  $293.15 \text{ K}$  and  $0.101 \text{ MPa}$  [202, 203]. Eight pure organic liquids were used as reference liquids to calibrate the apparatus. The thermal conductivity was determined to be  $\lambda = 0.32 \pm 0.03 \text{ W m}^{-1} \text{ K}^{-1}$  at  $293.5 \text{ K}$  and  $0.101 \text{ MPa}$ , in agreement with the previous measurements of Safarov and Zaripova [275]. The thermal conductivity was determined to change very little over the pressure range of  $0.101$ – $2.068 \text{ MPa}$ . The pressure dependence of the thermal conductivity was found to not vary within error of the experiment in a pressure range of  $0.101$  to  $2.068 \text{ MPa}$ . The measurement of the thermal conductivity of hydrazine as a function pressure by the transient hot-wire method demonstrated that pressures typical for on-orbit storage of hydrazine do not change the thermal conductivity much. Large inaccuracies were obtained when estimating the thermal conductivity of hydrazine using standard estimation methods that utilize velocity of sound data.

#### 2.1.13.3 Thermal Conductivity of Hydrazine Vapor

It is very difficult to measure the thermal conductivity of hydrazine vapor due to incipient decomposition. The thermal conductivity of hydrazine vapor was measured at  $800 \text{ Pa}$  ( $6 \text{ mm Hg}$ ) and  $298 \text{ K}$  and found to be  $3.49 \pm 0.04 \times 10^{-5} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1} = 1.4602 \times 10^{-2} \text{ W m}^{-1} \text{ K}^{-1}$  [276]. Previously it had been assumed that the thermal conductivity of hydrazine was similar to that of ethylene ( $\text{N}_2\text{H}_4 = \text{C}_2\text{H}_4$ ), when in fact it is not. The thermal conductivity of hydrazine is closer to that of methanol, which is also a polar molecule and has an identical molecular weight. Using the same temperature dependence as methanol, the thermal conductivity at  $6 \text{ mm Hg}$  and higher temperatures was extrapolated to be  $6.5$ ,  $7.5$ ,  $15$ , and  $30 \times 10^{-5} \text{ cal s}^{-1} \text{ cm}^{-1} \text{ }^{\circ}\text{C}^{-1}$  at  $373$ ,  $473$ ,  $773$ , and  $1273 \text{ K}$ , respectively. In another attempt, the thermal conductivity of hydrazine vapor was calculated using Bromley's correlation, with negligible contribution by internal rotation [102]. According to this correlation, thermal conductivity increases from  $10^{-5} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$  at  $273 \text{ K}$  to  $2 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$  at  $873 \text{ K}$  (assuming that hydrazine vapor is stable enough to survive this temperature).

#### 2.1.13.4 Thermal Conductivity of Hydrazine/Water Mixtures

It is not quite clear why the thermal conductivity of hydrazine hydrate solutions was measured up to very high pressures and very high temperatures and at concentrations substantially above those encountered where hydrazine hydrate is used to deoxygenate boiler feedwater. There may be other applications we do not know about yet. The thermal conductivity of hydrazine hydrate was measured from atmospheric

pressure to 49.05 MPa and from 293 to 553 K [180, 277]. The results (Figure 30) showed that the thermal conductivity increased with pressure and went through a maximum near 380 K. Further study showed that thermal conductivity correlated quite well with density, which also went through a maximum when plotted in relative units [275, 278].

**Figure 30:** Thermal conductivity of hydrazine hydrate at high pressures and temperatures. (Republished and modified from [277], with permission of ©1993 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

#### 2.1.14 Heat-Transfer Coefficient of Hydrazine

Knowledge of the heat-transfer characteristics of hydrazine is important in the design of injectors for rocket engines and gas generators using this propellant. Although at one time the XLR117-NA-1 rocket engine intended for use on the NOMAD upper stage apparently was regeneratively cooled with hydrazine and probably had to be purged with inert gas after each engine shutdown, by now most rocket engine designers have begun to realize that hydrazine cannot be used as a coolant in regeneratively cooled rocket engines. Not that it is a poor coolant; on the contrary, it is a good coolant, almost as good as water; it is just that during the heat soakback after shutting down the engine, the residual hydrazine in the cooling jacket and injector passages may explode. An excellent summary of the heat flux limits of several storable rocket propellants, including hydrazine, MMH, UDMH, and their mixtures, is provided in [279]. After previous futile – and, in part, disastrous – attempts to use anhydrous hydrazine as a cooling medium in regeneratively cooled rocket engines [280], nobody now seriously considers anhydrous hydrazine as suitable fuel in regeneratively fuel-cooled engines.

However, hydrazine can be used in film-cooled rocket engines. It was thus a significant improvement when the 50:50 mixture of hydrazine with UDMH (called Aerozine-50) was developed in the 1950s and proved to be a suitable regenerative coolant.

The heat-transfer characteristics of hydrazine flowing in electrically heated round tubes were studied at Rocketdyne [281–283]. Burnout heat flux and the effect of additives on explosive burnout were investigated. A total of 143 determinations of non-boiling convective heat transfer were made with hydrazine over the following range of conditions: liquid velocity 7–37 m/s (23–123 ft/s), bulk temperature 293–343 K (68–158 °F),  $\Delta T = T_{\text{wall}} - T_{\text{sat}} = 30 - 250$  K (55–450 °F), and pressures of 13.8–69 bar (200–1000 psia). Forced-convection results were correlated using dimensionless parameters by the equations due to McAdams or Sieder and Tate and by a statistical fitting of data to the general dimensionless equation

$$\nu = a \text{Re}^b \text{Pr}^c \left( \frac{T_W}{T_B} \right)^d$$

where  $\nu$  is the Nusselt number, Re the Reynolds number, Pr the Prandtl number,  $a$ ,  $b$ ,  $c$ ,  $d$  coefficients characteristic for each fluid, and  $T_W/T_B$  the wall:bulk temperature ratio. The temperature rather than the viscosity ratio was used because insufficient data on the viscosity of hydrazine at higher temperature were available at that time. A curve-fitting exercise gave the best fit of data when the following coefficients and exponents were used:

$$\nu = 0.00161 \text{Re}^{0.98} \text{Pr}^{0.86} \left( \frac{T_W}{T_B} \right)^{0.24}$$

The results of more than 80 tests in the nucleate boiling regime at pressures from 1.376 to 6.88 MPa (200 to 1000 psia), liquid velocities from 7.3 to 25.2 m/s (24–83 ft/s), and bulk temperatures from 313 to 400 K (104–259 °F) were scattered over a wide range, and no numerical relationship could be derived. The maximum superheat measured was  $\Delta T = 42$  K (76 °F). In determining the peak boiling heat flux, the wall temperatures were increased until burnout occurred.

Many of these tests were accompanied by explosions. As would be expected for any liquid, the peak flux was found to increase with decreasing feed temperature and increasing velocity. Whereas Bartz [284, 285] found little pressure effect over the range 2.06–8.26 MPa (300–1200 psia), the Rocketdyne tests showed a distinct pressure dependence between 4.82 and 6.88 MPa (700–1000 psia). The data for the maximum heat flux at burnout can be represented by the following two equations:

1. In BTUs:  $Q/A$  in  $\text{BTU in.}^{-2} \text{s}^{-1}$ ,  $h$  in  $\text{BTU in.}^{-2} \text{s}^{-1} \text{°F}^{-1}$ ,  $T$  in °F:

$$\frac{Q}{A} = -0.21 + 0.013(T_S - T_B) + h(T_W - T_B) \quad \text{at } p = 700 \text{ psia}$$

$$\frac{Q}{A} = -0.28 + 0.052(T_S - T_B) + h(T_W - T_B) \quad \text{at } p = 1000 \text{ psia}$$

2. In SI units:  $Q/A$  in  $\text{W/m}^2$ ,  $h$  in  $\text{W m}^{-2} \text{K}^{-1}$ ,  $T$  in K:

$$\frac{Q}{A} = -3.43 \times 10^5 + 3.82 \times 10^4 (T_S - T_B) + h(T_W - T_B) \quad \text{at } p = 4.82 \text{ MPa}$$

$$\frac{Q}{A} = -4.57 \times 10^5 + 1.53 \times 10^5 (T_S - T_B) + h(T_W - T_B) \quad \text{at } p = 6.88 \text{ MPa}$$

where  $h$ , the convective liquid film coefficient, must be calculated from the Nusselt number equation shown earlier and  $T_S$  is the saturation temperature.

Burnout with mixtures of hydrazine with ethanol, ethylene diamine, or UDMH occurred only at higher heat fluxes. These additives appeared to have a stabilizing effect on hydrazine.

Some typical experimental values of  $(q/A)_{\text{ul}}$  are listed in Table 23. As can be seen from the numbers for hydrazine, maximum heat-transfer rates are less than double when the linear flow speed is tripled.

**Table 23:** Heat flux for surface nucleate boiling of hydrazine at upper limit.

| Propellant                    | Pressure |      | Bulk temperature |     | Velocity |      | $(q/A)_{\text{ul}}$                   |                   |
|-------------------------------|----------|------|------------------|-----|----------|------|---------------------------------------|-------------------|
|                               | MPa      | psia | K                | °F  | m/s      | ft/s | BTU in. <sup>-2</sup> s <sup>-1</sup> | W/cm <sup>2</sup> |

Data sources: [282, 286]

Experimental data for hydrazine in Figure 31 are compared with predictions from the theoretical equation

$$(q/A)_{\text{ul}} = K\lambda\rho_v \left[ \frac{\sigma g_c g(\rho_L - \rho_v)}{\rho_v^2} \right]^{1/4} \left[ 1 + \left( \frac{\rho_L}{\rho_v} \right)^{0.923} \frac{C_L(T_S - T_L)}{25\lambda} \right] \\ + \left[ K' \frac{k}{D} \text{Re}^m \text{Pr}^n (T_W - T_L)_{\text{ul}} \right]$$

where  $K = \pi/24$ ,  $K' = 0.023$ ,  $m = 0.28$ ,  $n = 0.4$ ,  $\lambda$  is the latent heat of vaporization,  $\rho$  the density,  $\sigma$  the surface tension,  $g_c$  the universal constant ( $32.17 \text{ lb}_m \text{ ft lb}_f^{-1} \text{ s}^{-2}$ ),  $g$  the acceleration due to gravity,  $T_S$  the saturation temperature,  $T_W$  the wall temperature,  $T_L$  the fluid bulk temperature, and the subscript L is for liquid, V is for vapor, and ul is for the upper limit.

**Figure 31:** Peak heat flux for hydrazine flowing inside tubes. (Reproduced and modified from [286])

Considering the difficulty of measurements with near-boiling hydrazine, the agreement between experimental and theoretical data is reasonably good.

The upper limit of nucleate boiling ( $q_{ul}$ ) for hydrazine was measured for commercial-grade hydrazine in a range of 0.68 to 8.26 MPa (100 and 1200 psia), bulk temperatures from 292.5 to 445.9 K (67–343 °F), and velocities of 0.3–28.4 m/s (1–93 ft/s). Values of  $q$  ranged from  $1.09 \times 10^6$  to  $4.46 \times 10^7\ W/m^2$  (0.67 to 27.27  $BTU\ in^{-2}\ s^{-1}$ ) and can be represented by the following equation [274]:

$$q_{ul} = \left[ 1 - 0.236 \left( \frac{p - 675}{675} \right) \right]^2 \left[ 6.9 - 0.246v - T_b(0.015 + 2.7 \times 10^{-4} \times v) \right]$$

where  $p$  is the pressure in psia,  $v$  the velocity in ft/s,  $T_b$  the bulk temperature in °F, and  $q$  the heat flux in  $BTU\ in^{-2}\ s^{-1}$ . A less complicated equation is available that represents  $q_{ul}$  at 1.03–2.10 MPa (150–305 psia) and 0.6–9.4 m/s (2–31 ft/s), where it predicts  $q_{ul}$  more accurately than does the equation shown earlier:

$$q_{ul} = 5.98 + 0.304v - T_b(0.01175 + 5.47 \times 10^{-4}v)$$

The cooling capability of hydrazine was found to be far superior to that of any other storable rocket fuel tested at JPL up to that time, as long as the liquid was kept flowing and stagnant areas were avoided. A hydrazine mixture containing 10% ethylenediamine had slightly lower burnout limits than did pure hydrazine. Numerous attempts have been made to use hydrazine as a fuel in regeneratively cooled rocket engines, but many of these ended in disaster. There are several reports in the literature on previous efforts of this kind, but the reports are quite ancient and not easily accessible [280, 284, 287].

Burnouts due to exothermic reactions are characterized by an abrupt termination of the normal forced convection heat transfer. Generally, there is no warning of incipient burnout. There is no transition regime as with thermally stable fuels. There are significant contributions by sudden exothermic reactions in the boundary layer. Since these are associated with gas evolution, the quality of the liquid stream suffers at the same time. Catalytic contributions by the tube wall cannot be excluded. The  $q_{ul}$  in AMS 4130 steel tubes was as much as 75% lower than that in corrosion resistant eutectic steel (CRES) CRES-347 tubes; Al-52-SO, steel 17-7PH, Hastelloy-C, nickel braze, and even copper tubes behaved like CRES in these tests [274].

Scattered ultimate heat-flux data are available for hydrazine mixtures containing 5, 10, or 12% ethanol or 5% ammonia [279]. None of these additives improved the burnout limitations of hydrazine.

The heat flux at the upper limit of nucleate boiling was determined for two hydrazine-UDMH mixtures containing 50 and 77% hydrazine [288]. Nominal test conditions for the 50:50 mix ranged from 3.78 to 7.57 MPa fluid static pressure, 9.1–27 m/s fluid velocity, and 311–366 K liquid bulk temperature. The other mix was investigated only over a narrower range from 3.78 to 6.19 MPa and at two bulk temperatures, 333 and 366 K. Testing was done in an electrically heated CRES-347 tube with 6.3-mm outer diameter (O.D.) and 0.22-mm walls. The heated section was 75 mm long. The transition from nucleate to film boiling manifested itself experimentally by a sudden large increase in the tube-wall temperature. In most cases, the temperature rise resulted in a loss of tube-wall strength, and the test section would rupture before the heater power could be turned off. The  $q_{ul}$  of the 50:50 mix was typically 65% of that previously determined for pure hydrazine under similar conditions. The  $q_{ul}$  ranged from 229 to 638 cal cm<sup>-2</sup> s<sup>-1</sup> (5.85 to 16.33 BTU in.<sup>-2</sup> s<sup>-1</sup>). The numerical data can be approximated by the equation

$$q_{ul} = 7.86 - 4.93 \times 10^{-3}(p - 1100) + 0.1343(V - 50) - 1.20 \times 10^{-2}(T_L - 160)$$

where  $q_{ul}$  is the upper limit of nucleate boiling in BTU in.<sup>-2</sup> s<sup>-1</sup>,  $p$  the static fluid pressure in psia,  $V$  the fluid velocity in ft/s, and  $T_L$  the bulk temperature in °F. Ninety-five percent of the test data were within  $\pm 15\%$  of the  $q_{ul}$  dependence calculated using this equation. The mixture containing 77% hydrazine and 23% UDMH had upper limits at 77% of those of hydrazine. Demonstrated upper-limit heat fluxes ranged from  $1.31 \times 10^7$  to  $3.06 \times 10^7$  W/m<sup>2</sup> ( $312$ – $732$  cal cm<sup>-2</sup> s<sup>-1</sup> = 8 to 18.7 BTU in.<sup>-2</sup> s<sup>-1</sup>). Some of the older

reports on the heat-transfer properties of liquid hydrazine are more difficult to obtain [289].

### 2.1.15 Critical Point Constants of Hydrazine

For thermally stable fluids, it is often possible to determine the critical constants experimentally. This is not possible for hydrazine because it begins to decompose already at temperatures substantially below the critical temperature. Critical point parameters can be extrapolated from other physical and thermodynamic properties.

In some extreme cases of heat transfer to hydrazines at very high pressures and very high temperatures, the conditions may momentarily approach the critical point and reach supercritical conditions where totally different physical laws govern heat transfer. While this regime is well explored for water, liquid hydrogen, and other thermally stable fluids, very little information is available on hydrazines under supercritical conditions. The critical constants of hydrazine(s) are very difficult to determine because the liquid usually undergoes decomposition before the critical point is reached. Audrieth [7] on page 57 reported a critical temperature of 653 K (380 °C) for hydrazine based on the archaic work by [169]. The corresponding critical pressure given was 1.469 MPa = 145 atm = 2131 psia. Both sets of data are probably not very accurate. In the words of Audrieth: “*There is some question about the accuracy of the critical constants in view of the known tendency of hydrazine to undergo decomposition at higher temperatures.*” The data do not get more reliable each time they are quoted and passed on to the next generation of chemists. Most critical point data for hydrazine(s) are calculated from other physical and thermodynamic properties measured under noncritical conditions.

A critical review of critical point data [105] was unable to locate any more recent or more reliable data other than the ancient data traced back to Audrieth and de Bruyn. The set of critical point data chosen by Giordano for further calculations was  $T_c = 653.15$  K,  $p_c = 14.69$  MPa, and  $V_c = 4.335 \times 10^{-3}$  m<sup>3</sup>/kg. This is similar to critical point data derived by Das and Ausloos in 1968:  $T_c = 653.16$  K,  $p_c = 14.69$  MPa = 145 atm,  $\rho_c = 0.1389$  L/mol = 7.199 mol/L = 230.7 g/L = 0.2307 g/cm<sup>3</sup> = 4.335 cm<sup>3</sup>/g.

## 2.2 Thermodynamic Properties of Hydrazine

Hydrazine might still be an obscure chemical with few applications were it not for its unique enthalpy of formation, which is positive, such that on decomposition of hydrazine to its elements and a little ammonia, a good amount of useful energy is released. Thermochemical properties such as heat capacity, heat of formation, heat of combustion, heat of vaporization, and other thermal characteristics are needed to calculate the useful energy derived from hydrazine in several industrial applications, including rockets.

There are several summary publications with thermodynamic property data for hydrazine. The most thorough review was performed by Giordano [105]. The summary by Das and Kuloor in 1968 [173] contained eight pages of tabulated data for the specific volume, enthalpy, and entropy of hydrazine liquid and vapor and presented a full-page temperature-entropy diagram, the only one in the entire literature. The thermodynamic data used most often for rocket performance calculations are the JANNAF tables [290]. The JANNAF tables usually contain one page discussing the source of data, but it is incomplete. The curators of the NIST Chemistry WebBook web site [291] have done an incomplete job in summarizing and evaluating existing thermodynamic data. Nevertheless, the NIST Chemistry WebBook data are referenced here in our summary. See also [292].

### 2.2.1 Heat Capacity of Hydrazine

#### 2.2.1.1 Heat Capacity of Liquid Hydrazine

Whereas heat capacity data for ideal vapors can be calculated from IR or microwave spectroscopic data, heat capacity determination of liquids and solids depends on calorimetric measurements, which are usually less accurate. Heat capacities are important for the calculation of temperature changes in hydrazines during industrial processes. The heat capacity data are also required for the conversion of standard enthalpies and entropies of formation to other temperatures (other than 298 K).

Multiple determinations of the heat capacity of hydrazine have been made over the past century, but not all have yielded reliable data. It is difficult to decide in retrospect which data are the most reliable to use for future work. The most thorough critical examination of heat capacity data was done by Giordano in 2001.

In reviewing heat capacity data for hydrazine, we have attempted to arrange them in chronological order. That is not necessarily the same sequence they would be in if ranked by degree of reliability.

Data on the heat capacity of liquid hydrazine are available from at least three sources. Some data are for anhydrous (laboratory-prepared) hydrazine, [107, 176], whereas other data are for propellant-grade hydrazine [293]. Because propellant-grade hydrazine contains some impurities, the results differ slightly.

The heat capacity of a hydrazine sample presumed to be at least 99.75% by weight was measured at 12–340 K [107] (Table 24). The phase change at 274.69 K was associated with a melting enthalpy of 12.657 kJ/mol (3.025 kcal/mol = 94.4 cal/g).

The heat capacity is a function of the pressure, and results would be different if measurements were conducted at saturation pressure or under truly isobaric conditions. The heat capacity data by Hough, Mason, and Sage [176] for liquid hydrazine were lower than those reported by Scott et al. [107] over the entire range of data, with the maximum deviation (–1.0%) occurring at 313 K. If one combines the two sets of data and applies a curve-fitting method, the following equation will represent the best

combination of heat capacity data for liquid hydrazine [171]:

$$c_p = 0.88415 - 1.3949 \times 10^{-3}T + 3.0074 \times 10^{-6}T^2$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin, or

$$c_p = 3.6993 - 5.8363 \times 10^{-3}T + 1.2583 \times 10^{-5}T^2$$

where  $c_p$  is the heat capacity in  $\text{J g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin.

The sample used by Ahlert and Younts [293] for measurements in a range of 331 to 464 K was a propellant-grade hydrazine containing 2.5%  $\text{H}_2\text{O}$ , 0.5%  $\text{NH}_3$ , and traces of aniline and heptane. The heat capacity measurements were made in a counterflow heat exchanger under dynamic conditions. At the highest temperature, hydrazine decomposition became noticeable. Therefore, a correction for heat released by decomposition was applied. The heat capacity of this fuel was up to 1.3% higher than that of pure hydrazine, and the slope of the straight-line function was 1.5% less steep in the overlapping temperature range. A linear least-squares fit of the Ahlert and Younts data gave an equation valid for the range from 331 to 464 K

$$c_p = 0.734 + 5.33 \times 10^{-4}t$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{K}^{-1}$  and  $t$  is the temperature in  $^{\circ}\text{C}$ . Other sources ([171], see Equation 2.3-16) represent the same Ahlert and Younts [293] data for a propellant-grade hydrazine by a more sophisticated equation (a higher-order polynomial fit):

$$c_p = 0.29512 + 2.0193 \times 10^{-3}T - 1.8559 \times 10^{-6}T^2$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin, which corresponds to

$$c_p = 1.2348 + 8.4487 \times 10^{-3}T - 7.7651 \times 10^{-6}T^2$$

in SI units, where  $c_p$  is the heat capacity in  $\text{J g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. Curve-fitting JANNAF data gave the following equation for liquid hydrazine from 100 to 800 K [208]:

$$C_p = 80.957 + 5.2929 \times 10^{-2}T + 3.384 \times 10^{-5}T^2$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin, or, in mass units,

$$c_p = 2.5263 + 1.6517 \times 10^{-3}T + 1.056 \times 10^{-6}T^2$$

where  $c_p$  is the heat capacity in  $\text{J g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin.

Data on the heat capacity of pure liquid hydrazine are also contained in the following section on the heat capacity of hydrazine mixtures. The reader in search of hydrazine data is thus advised to review the following data on hydrazine mixtures

as well. Additional molar heat capacity data on liquid and gaseous hydrazine are contained in Tables 24 and 28, together with the heat of formation and other thermochemical data. See also [294].

### 2.2.1.2 Heat Capacity of Hydrazine Vapor

Some of the first heat capacity data derived from IR spectra of hydrazine vapor were those reported by Fresenius and Karweil [217] and Eucken and Krome [295]. The data from the two sources at 313 and 340 K (40 and 67 °C) were in good agreement.

Averaging experimental data from Fricke [210] and Scott et al. [107], as was done by Haws and Harden [172], the following polynomial function was obtained for the heat capacity of hydrazine vapor, but it turned out to be inconsistent with data shown in Table 3, Column 3 of Haws and Harden [172], a mistake that unfortunately was carried through two editions of the hydrazine book without being corrected in a timely manner. The incorrect equation is shown here as a warning (Do not use!):

$$c_p = 0.137857 + 5.2715 \times 10^{-5} T - 1.19907 \times 10^{-7} T^2$$

where  $c_p$  was the heat capacity in unspecified units and  $T$  was the temperature in unspecified units. This equation cannot be made to fit the Table 3, Column 3 data by assuming the temperature units are °C, °F, K, or °R or by changing the minus sign between the second and third terms to a plus sign.

JANNAF heat capacity data for hydrazine vapor from 300 to 1000 K [290] can be curve-fitted by equations derived by [208]:

$$C_p = 31.8832 - 5.397 \times 10^{-3} T + 3.13325 \times 10^{-4} T^2 - 4.16306 \times 10^{-7} T^3 + 1.69082 \times 10^{-10} T^4$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin, or, in mass units,

$$c_p = 9.9495 \times 10^{-1} - 1.6842 \times 10^{-4} T + 9.7777 \times 10^{-6} T^2 - 1.2991 \times 10^{-8} T^3 + 5.2764 \times 10^{-12} T^4$$

where  $c_p$  is the heat capacity in  $\text{J g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin.

### 2.2.1.3 Heat Capacity of Solid Hydrazine

Frozen hydrazine is not a good rocket propellant. Frozen hydrazine usually signifies a problem that may jeopardize mission success or even constitute a hazard to the population at large. The mission success of SOHO was in limbo for several months while hydrazine in propellant tanks was frozen [296]. A military satellite, referred to as USA 193, was launched into a low orbit in December 2006 but went out of control soon after, causing its load of hydrazine to freeze. There was concern that the chunk of frozen hydrazine in a spherical tank could survive uncontrolled re-entry in populated areas, so the satellite was shot down in February 2008 as a preventive measure. Calculations predicting the survival of the chunk of hydrazine needed to be based on the heat capacity and the heat of fusion of solid hydrazine.

**Table 24:** Heat capacity of solid and liquid hydrazine.

| Temperature                         |       |       | Heat capacity                         |       |                        |
|-------------------------------------|-------|-------|---------------------------------------|-------|------------------------|
| K                                   |       |       | K                                     |       |                        |
| J mol <sup>-1</sup> K <sup>-1</sup> |       |       | cal mol <sup>-1</sup> K <sup>-1</sup> |       |                        |
| Solid                               |       |       | Liquid                                |       |                        |
| 12                                  | 0.29  | 0.07  | 90                                    | 28.12 | 6.72                   |
| 13                                  | 0.39  | 0.095 | 95                                    | 29.54 | 7.06                   |
| 14                                  | 0.48  | 0.115 | 100                                   | 30.86 | 7.375                  |
| 15                                  | 0.58  | 0.14  | 110                                   | 33.39 | 7.98                   |
| 16                                  | 0.69  | 0.165 | 120                                   | 35.73 | 8.54                   |
| 17                                  | 0.86  | 0.205 | 130                                   | 37.95 | 9.07                   |
| 18                                  | 1.05  | 0.25  | 140                                   | 40.04 | 9.57                   |

Data source: [107]

The only complete set of heat capacity data for solid hydrazine is the ancient one based on the data by Scott et al. from 1949 [107], summarized in Table 24. Audrieth and Ackerson-Ogg [7], pages 68–69, have developed six different curve-fitted equations that can be used to calculate the heat capacity in selected temperature ranges and can be used to integrate for the enthalpy changes in frozen hydrazine as it warms or cools between different temperatures.

No other experimental determination of solid N<sub>2</sub>H<sub>4</sub> specific heat has ever been attempted since the Scott et al. [107] investigation. There have been examinations of

density, compressibility, and thermal conductivity of solid hydrazine [113], but no further work on heat capacity.

#### 2.2.1.4 Heat Capacity of Hydrazine/Water Mixtures

Hydrazine/water mixtures are encountered during the production of hydrazine (hydrate) and need to be concentrated and dehydrated before a useful rocket propellant is obtained. Some hydrazine/water mixtures with 70% hydrazine are used as monopropellants in gas generators. The formation of unusual hydrates and associated clusters at certain hydrazine:water ratios, which already documented itself in unusual melting-point and viscosity behavior, is also partially reflected in the heat capacity of such mixtures. Hydrazine concentrations in boiler feedwater or in fuel cells are much lower than those in rocket propellants, but the physical properties of dilute solutions are included here and in many other publications.

The specific heats of hydrazine/water mixtures at the bubble-point pressure were determined in a stainless-steel bomb calorimeter for mixtures containing 48.3, 70.4, 90.3, and 99.9 mass-% hydrazine in water [297]. The temperature ranges for these mixtures were approximately 328 to 361 K, 316 to 361 K, 300 to 344 K, and 294 to 328 K (130 to 190, 110 to 190, 80 to 160, and 70 to 130 °F), respectively. This experiment should have included the 64%  $\text{N}_2\text{H}_4$  mixture, which corresponds to HH100. The heat capacity data of the binary hydrazine/water system are summarized in Table 25, which also shows data for pure hydrazine.

**Table 25:** Isobaric heat capacity of liquid hydrazine/water mixtures.

<sup>a</sup> Smoothed values.

Data Source: [176]

The data at 294.8 K (71 °F) are 0.03 cal/g higher than those reported by Scott et al. In a first, crude approximation, the heat capacity data of Table 25 can be represented by

$$c_p = 1.1300 - 0.26551X - 4.15746 \times 10^6 T^{-3}$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{°C}^{-1}$ ,  $X$  is the weight fraction of hydrazine, and  $T$  is the temperature in kelvin. An alternative curve fit gave

$$c_p = 0.54994 + 0.36032X - 1.8398 \times 10^{-3}XT + 1.8398 \times 10^{-3}T \\ - 1.73667 \times 10^7 T^{-3} + 3.85528 \times 10^9 T^{-4}$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{°C}^{-1}$ ,  $X$  is the weight fraction of hydrazine, and  $T$  is the temperature in kelvin. Neither of the two equations matches the data in Table 25 accurately, and they deviate after the second place after the decimal point. The heat capacities of comparatively dilute solutions (up to 0.69 molal  $\text{N}_2\text{H}_5\text{OH} = 2.18 \text{ mass-}\% \text{ N}_2\text{H}_4$ ) were determined as part of a study on the heats of solution of hydrazine in water, the apparent molal heat capacity of the mixture, and partial molal heat capacities of the solute and the solvent [298]. These data, summarized in Table 26, cover only the lower end of the concentration range of hydrazine-water mixtures.

**Table 26:** Heat capacity of dilute hydrazine hydrate solutions.

<sup>a</sup> Number of mols of  $\text{N}_2\text{H}_5\text{OH}$  per 55.508 mols of unreacted water.

Data source: [298]

Hydrazine has been used as a “diluent” for water in an effort to study the abnormal heat capacity behavior of supercooled water as its temperature approaches 228 K. The heat capacity of hydrazine/water mixtures was determined in a differential scanning calorimeter [299, 300]. Most of the interpretation of the data was concerned with the

effect of water rather than hydrazine in the mixture, as well as in comparison with the effect of hydrogen peroxide. The isotherms for the molar heat capacity of solutions are shown in Figure 32. The shape of the 240 K isotherm is truly extraordinary because heat capacity increases rapidly as the concentration approaches zero per cent hydrazine. This deviation from ideality has been attributed to the formation of association structures like those found in supercooled water [301]. Similar structures are most likely also responsible for the tendency of hydrazine/water mixtures to form viscous mixtures and glassy solids on approaching the freezing point, making it very difficult to determine freezing points and melting points of such mixtures.

**Figure 32:** Heat-capacity isotherms for water/hydrazine solutions. (Reproduced and modified from [300].)

Most publications deal only with the heat capacity of hydrazine solutions as a function of concentration and temperature. Additional investigations have also studied the effect of pressure on heat capacity of hydrazine solutions. High pressures may be encountered in steam power plants, although the hydrazine concentrations in boiler

feedwater are usually only very low. The heat capacity (thermal capacity) of aqueous hydrazine hydrate solutions in the temperature range 313–450 K and pressure range 0.101–49.1 MPa was measured, and generalized equations were obtained to calculate the thermal capacities of these solutions [302, 303]. The measurements were made along isobars with pressure steps of 4.9–9.8 MPa. The heat capacity of a solution containing 90% hydrazine hydrate and 10% water at 293 K decreased from  $3032 \text{ J kg}^{-1} \text{ K}^{-1}$  at 0.101 MPa down to  $2986 \text{ J kg}^{-1} \text{ K}^{-1}$  at 49 MPa. The heat capacity as a function of temperature at atmospheric pressure increased linearly with temperature from  $3032 \text{ J kg}^{-1} \text{ K}^{-1}$  at 293 K to  $3120 \text{ J kg}^{-1} \text{ K}^{-1}$  at 343 K.

### 2.2.2 Enthalpy of Formation of Hydrazine

Exact knowledge of thermodynamic data, including enthalpy of formation, free energy of formation, and entropy is important for the calculation of the theoretical performance of hydrazine in several practical applications, such as rocket engines or fuel cells. Besides from calorimetric determinations, these data are usually obtained from IR, Raman, or microwave spectroscopic observations and calculation of molecular vibrations. This requires knowledge of the structure of the hydrazine molecule, which is discussed in more detail in Section 2.3. See also [304, 305].

#### 2.2.2.1 Enthalpy of Formation of Hydrazine Liquid

Various numbers, not always in agreement, have been reported for the enthalpy of formation of liquid anhydrous hydrazine in recent decades. Historical data are summarized in Table 27.

**Table 27:** Comparison of enthalpy of formation data for liquid hydrazine.

| Enthalpy of formation |          |        | References |
|-----------------------|----------|--------|------------|
| kJ/mol                | kcal/mol | cal/g  |            |
| +50.41                | +12.049  | +376   | [306]      |
| +53.76                | +12.85   | +401   | [306]      |
| +50.38                | +12.041  | +375.7 | [307]      |
| +50.63                | +12.101  | +377.6 | [291]      |

Molecular mass: 32.0452 g/mol

The first accurate determination of the enthalpy of formation of liquid hydrazine was performed in 1939 using the heat of combustion measured in a calorimeter [308]. The heat of reaction when forming hydrazine hydrate from liquid hydrazine and liquid water is  $(\Delta H)_{298} \text{ N}_2\text{H}_5\text{OH(L)} = 43.09 \text{ kJ/mol}$  (10.30 kcal/mol), but the heat of formation of hydrazine hydrate from the elements is  $-209 \text{ kJ/mol}$  ( $-58.018 \text{ kcal/mol}$ ). There has been some confusion about the definition of the enthalpy of formation of hydrazine

hydrate in the literature, and earlier books contained incorrect numbers. The experimentally measured heats of combustion at 298 K were  $19404 \pm 4.6 \text{ J/g}$  ( $4637.6 \pm 1.1 \text{ cal/g}$ ) and  $12281 \pm 2.5 \text{ J/g}$  ( $2935.2 \pm 0.6 \text{ cal/g}$ ) for hydrazine and hydrazine hydrate, respectively. Depending on which heat of combustion is used, two slightly different enthalpies of formation of anhydrous hydrazine can be obtained. With a standard heat of formation of  $\text{H}_2\text{O}(\text{L}) = -68.315 \text{ kcal/mol}$  ( $-285.83 \text{ kJ/mol}$ ), a standard heat of formation of  $(\Delta H)_{298}^{\text{f}} \text{N}_2\text{H}_4(\text{L}) = 50.229 \text{ kJ/mol} = +12.005 \text{ kcal/mol}$  is obtained from the first number. With the heat of hydration of hydrazine from [298] and the second number, an enthalpy of formation of  $(\Delta H)_{298}^{\text{f}} \text{N}_2\text{H}_4(\text{L}) = +50.639 \text{ kJ/mol} = +12.103 \text{ kcal/mol}$  is obtained. An average of these two sets of data would be  $(\Delta H)_{298}^{\text{f}} \text{N}_2\text{H}_4(\text{L}) = +50.434 \text{ kJ/mol} = +12.054 \text{ kcal/mol}$ , a value that is recommended by numerous authors.

The heat of combustion of hydrazine was measured as  $629.68 \text{ kJ/mol}$  ( $150.497 \text{ kcal/mol}$ ) in a calorimeter, corrected for 298 K [309]. In the same apparatus, a heat of combustion of MMH was measured as  $1303$  to  $1305 \text{ kJ/mol}$  ( $311.5$  to  $311.8 \text{ kcal/mol}$ ). A later measurement in the same apparatus gave a heat of combustion of hydrazine of  $621.8 \text{ kJ/mol}$  ( $148.619 \text{ kcal/mol}$ ), corrected for 298 K [310].

Sets of thermodynamic properties have been reported as compiled in Table 28. This table also contains data on a few hydrazine salts. The origin of some of these data is not quite clear, but it is assumed that the National Bureau of Standards has checked them for accuracy.

An excellent summary of the thermodynamic data on hydrazine, including data on the heat of formation and liquid-vapor phase change, was presented in a series of papers [103–106]. On closer examination of data published earlier, several inconsistencies were discovered. Some of the inconsistencies may be a result of the low quality of anhydrous hydrazine used by some of the early investigators. Despite the widespread use of hydrazines, very few thermochemical data have been determined within the last 30 years. Many of the older data need to be verified using modern methods of calorimetry and pure starting materials. Another source of potential errors for the EOSs derived from the PVT data is the indiscriminate use of “bastard” units, mixing metric and nonmetric units in the same equation.

### 2.2.2.2 Enthalpy of Formation of Hydrazine Vapor

Using the enthalpy of formation of the liquid and the antiquated heat of vaporization ( $42.677 \text{ kJ/mol} = 10.2 \text{ kcal/mol}$  at 298 K) from [206], the heat of formation of hydrazine vapor was calculated as  $(\Delta H)_{298}^{\text{f}} \text{N}_2\text{H}_4(\text{G}) = +93.09 \text{ kJ/mol} = +22.25 \text{ kcal/mol}$  by Hughes, Corruccini, and Gilbert 1939, which was in good agreement with a classical, theoretical calculation by Pauling [312],  $+92.5 \text{ kJ/mol}$  ( $+22.10 \text{ kcal/mol}$ ), and with later determinations by Scott [107]:  $+95.2 \text{ kJ/mol}$  ( $+22.75 \text{ kcal/mol}$ ). NIST Chemistry WebBook lists the  $(\Delta H)_{298}^{\text{f}} \text{N}_2\text{H}_4(\text{G})$  as  $+95.35 \text{ kJ/mol}$  [291].

**Table 28:** Thermodynamic properties of hydrazine compounds.

| Compound                                                      | $(\Delta H)^f_{298}$ |          | $(\Delta G)^f_{298}$ |          | $S^0_{298}$                          |                                        | $C^0_{p, 298}$                       |                                        |
